Purpose: This study assessed the predictive value of the preoperative systemic immune-inflammatory index (SII) for lymph node metastasis (LNM) in endometrial cancer (EC) patients.

Methods: We retrospectively included 392 EC patients between January 2013 and January 2019. Data on clinical indicators including age, body mass index (BMI), menopause, serum inflammatory immune index, serum tumor markers, history of diabetes and hypertension, stage, histological type, and myometrial invasion (MI) were collected. The association between clinical indicators and LNM was evaluated.

Results: The results indicated that neutrophil (NE), monocyte (MO) counts, SII, cancer antigen 125 (CA125), cancer antigen 153 (CA153), cancer antigen 199 (CA199), and the expression of estrogen receptor (ER) and Ki67 were higher in EC patients with LNM than in those without LNM ($P < 0.05$). Lymph vascular space invasion (LVSI) was also associated with LNM ($P < 0.05$). Consequently, the SII, CA125, CA153 and LVSI were found to be independent risk factors for LNM, and a nomogram including these indicators was performed. The ROC curve analysis showed that compared with a single index, the combination of the SII, CA125, CA153 and LVSI significantly improved the efficiency of diagnosing LNM in EC patients ($AUC = 0.865$, $P < 0.001$). Moreover, the SII was significantly associated with age, menopause, and FIGO stage ($P < 0.05$). Further logistic regression analysis suggested that elevated serum SII was an independent risk factor for MI and progression to a higher pathological grade in young premenopausal EC patients. In addition, elevated SII was an independent risk factor for advanced EC progression in age ≥ 55 or postmenopausal EC patients.

Conclusion: An elevated SII is an independent risk factor for LNM in patients with EC. In addition, the SII can be used as a predictor of MI and higher pathological grade in young premenopausal EC patients.

Keywords: systemic immune-inflammatory index, neutrophil, platelet, lymphocyte count, lymph node metastasis, endometrial cancer

Introduction

Endometrial cancer (EC) is one of the most common malignant tumors of the female reproductive tract, with a lymph node metastasis (LNM) rate ranging from 10.5% to 14.9%.¹⁻³ LNM is an important factor influencing the poor prognosis of EC patients, which not only affects the pathological stage of surgery but also may lead to serious consequences such as recurrence and distant metastasis, thus reducing the long-term survival rate of patients.^{3,4} Surgery is the preferred treatment for

EC, and the basic surgical methods include cytological examination with retention of peritoneal fluid, laparoscopic extrafascial hysterectomy, bilateral adnexectomy, and abdominal aorta and pelvic lymph node dissection.⁴ However, the need for para-aortic and pelvic lymph node dissection in patients with low-risk and stage IA EC remains controversial. Some scholars believe that standardized lymph node dissection not only has auxiliary value in diagnosing LNM in patients with EC but also provides guidance for standardized postoperative treatment, which can reduce postoperative pelvic recurrence.^{5,6} However, some scholars believe that lymph node dissection does not improve the survival rate and tumor-free survival of patients but does cause lower limb pain, urinary fistula, bladder fistula and other postoperative complications in EC patients after surgical treatment.^{7–9} Therefore, preoperative overall evaluation is necessary. At present, imaging and tumor marker detection are the main methods for evaluating LNM in patients with EC. Imaging diagnosis is the clinical preoperative assessment of LNM in patients with EC, and the commonly used methods, such as ultrasonography, computerized tomography (CT), and magnetic resonance imaging (MRI), are affected by factors such as instruments and doctor experience. Hence, there is a certain probability of missed diagnosis and misdiagnosis. Cancer antigen 125 (CA125) is a tumor marker with good sensitivity closely related to the prognosis of EC, especially in EC patients with abdominal metastasis.¹⁰ Many studies have shown that CA125 can predict LNM in EC.¹¹ However, the level of serum CA125 can increase to varying degrees, such as in endometriosis¹² and hepatitis,¹³ which indicates that the specificity of CA125 as a tumor marker for EC is not high. Therefore, it is of great significance to actively seek scientific and effective LNM prediction methods for the formulation of treatment plans for patients with EC.

In recent years, the tumor microenvironment has received increasing attention, and a variety of inflammatory cells and inflammatory mediators are important components of the tumor microenvironment. Many studies have demonstrated that the systemic inflammatory response is related to the postoperative survival of tumor patients.^{14–17} Serum inflammatory factors can be detected in an easy and convenient way. Recently, the SII based on peripheral lymphocyte (Lym), neutrophil (NE) and platelet (PLT) counts has been considered a better index to reflect the local immune response and systemic inflammation, as its high prognostic value has been confirmed in a variety

of tumors, such as cervical cancer,¹⁵ pancreatic cancer,¹⁶ and colorectal cancer.¹⁷ Moreover, the SII has also been shown to be closely associated with poor prognosis of EC.^{18,19} However, the relationship between the SII and LNM in EC patients remains unclear.

Therefore, this study evaluated the relationship between the SII and LNM in EC patients to identify a suitable indicator for clinicians to use when performing preoperative risk assessments of LNM in EC patients to aid in clinical diagnosis and treatment.

Patients and Methods

Subjects

The current study retrospectively included patients who underwent primary hysterectomy for EC at Fujian Provincial Maternity and Children's Hospital from January 2013 to January 2019 and had immunohistochemical pathological results.

The exclusion criteria included the following: 1) other malignant tumors or a history of other malignant tumors (n=3); 2) acute or chronic inflammation, immune disease, or hematologic disease (n=4); 3) preoperative chemotherapy, radiotherapy or hormone therapy (n=0); and 4) loss to follow-up (n=5). A total of 392 patients were included. We obtained informed consent from all the included patients. The Ethics Committee of Fujian Provincial Maternity and Children's Hospital approved the study.

Data Collection and Definitions of Systemic Inflammatory Indexes

Data on demographic and clinical indicators were collected from the Fujian Provincial Maternity and Children's Hospital information system. This information included age, body mass index (BMI), white blood cell (WBC), NE, monocyte (MO), PLT, Lym, T cell, B cell, CD4+T Lym, CD8+T Lym, and NK cell counts, cancer antigen 125 (CA125), cancer antigen 199 (CA199) and 153 (CA153), and carcinoma embryonic antigen (CEA) levels, menopausal status, history of diabetes and hypertension, International Federation of Gynecology and Obstetrics (FIGO) stage, histological type, tumor grade, myometrial invasion (MI), lymphovascular space invasion (LVSI), LNM, and the expression levels of estrogen receptor (ER), progesterone receptor (PR), and Ki67. Blood testing was carried out within 1 week before surgery.

The inflammatory indexes were calculated as preoperative inflammatory indicators with the following formulas: $SII = PLT \text{ count} \times NE \text{ count} / Lym \text{ count}$.

Statistical Analysis

Statistical analysis was performed with SPSS 22.0 (IBM Corp., Armonk, NY, USA) and R version 4.0.2. Continuous variables were analyzed by Student's *t*-tests or Mann-Whitney *U*-tests. Chi-square tests or Fisher's exact tests were used to analyze the categorical variables. A receiver operating characteristic (ROC) curve was generated for the cutoff point of the continuous data. The areas under the curve (AUCs) are provided with their sensitivity, specificity, and 95% confidence intervals (CIs). The significance of the obtained cutoff values associated with EC was tested by performing both univariate and multivariate binary logistic regression analyses. Adjusted risk estimates were obtained with logistic regression models and accounted for the variables used for matching. A nomogram was constructed via the rms R package.

Validation of the nomogram included calibration and discrimination. Calibration was evaluated by calibration plots and Hosmer-Lemeshow tests to calculate the consistency between the observed and predicted probabilities. A Hosmer-Lemeshow *P* value > 0.05 indicated good consistency. The discrimination—namely, the predictive accuracy of a nomogram—was evaluated by the ROC curve. Significance was set at $P \leq 0.05$.

Results

Baseline Characteristics

Table 1 and Figure 1 show the clinical indicators associated with LNM in EC patients. The results indicated that serum inflammatory factors, including NE and MO counts and the SII, were higher in EC patients with

Table 1 Baseline Characteristics of EC Patients

LNM than in those without LNM ($P < 0.05$, Figure 1). In addition, the levels of serum CA125, CA153, and CA199 were elevated in the LNM group ($P < 0.05$, Table 1). Moreover, the expression of ER and Ki67 was higher in EC patients with LNM ($P < 0.05$, Table 1). LVSI was also associated with LNM ($P < 0.05$, Table 1). There were no differences observed between the EC patients with and without LNM with respect to age, BMI, WBC, Lym, PLT, T cell, B cell, CD4+ T cell, CD8+ T cell, NK cell counts, CEA level, menopausal status, history of diabetes and hypertension, or PR expression (all $P > 0.05$, Table 1, Figure 1).

Independent Risk Factors for LNM in EC Patients

The continuous data were dichotomized for subsequent analyses using ROC curve analysis and the Youden Index (Figure 2). The cutoff values for statistically significant LNM-related indicators, including NE, MO, SII, CA125, CA199, CA153, and Ki67, were identified. Moreover, the results of ROC curve analysis showed that these indicators had good predictive ability for LNM in EC (all $P < 0.05$, Figure 2). All baseline characteristics and clinicopathological features were analyzed by univariate and multivariate logistic regression analyses in EC

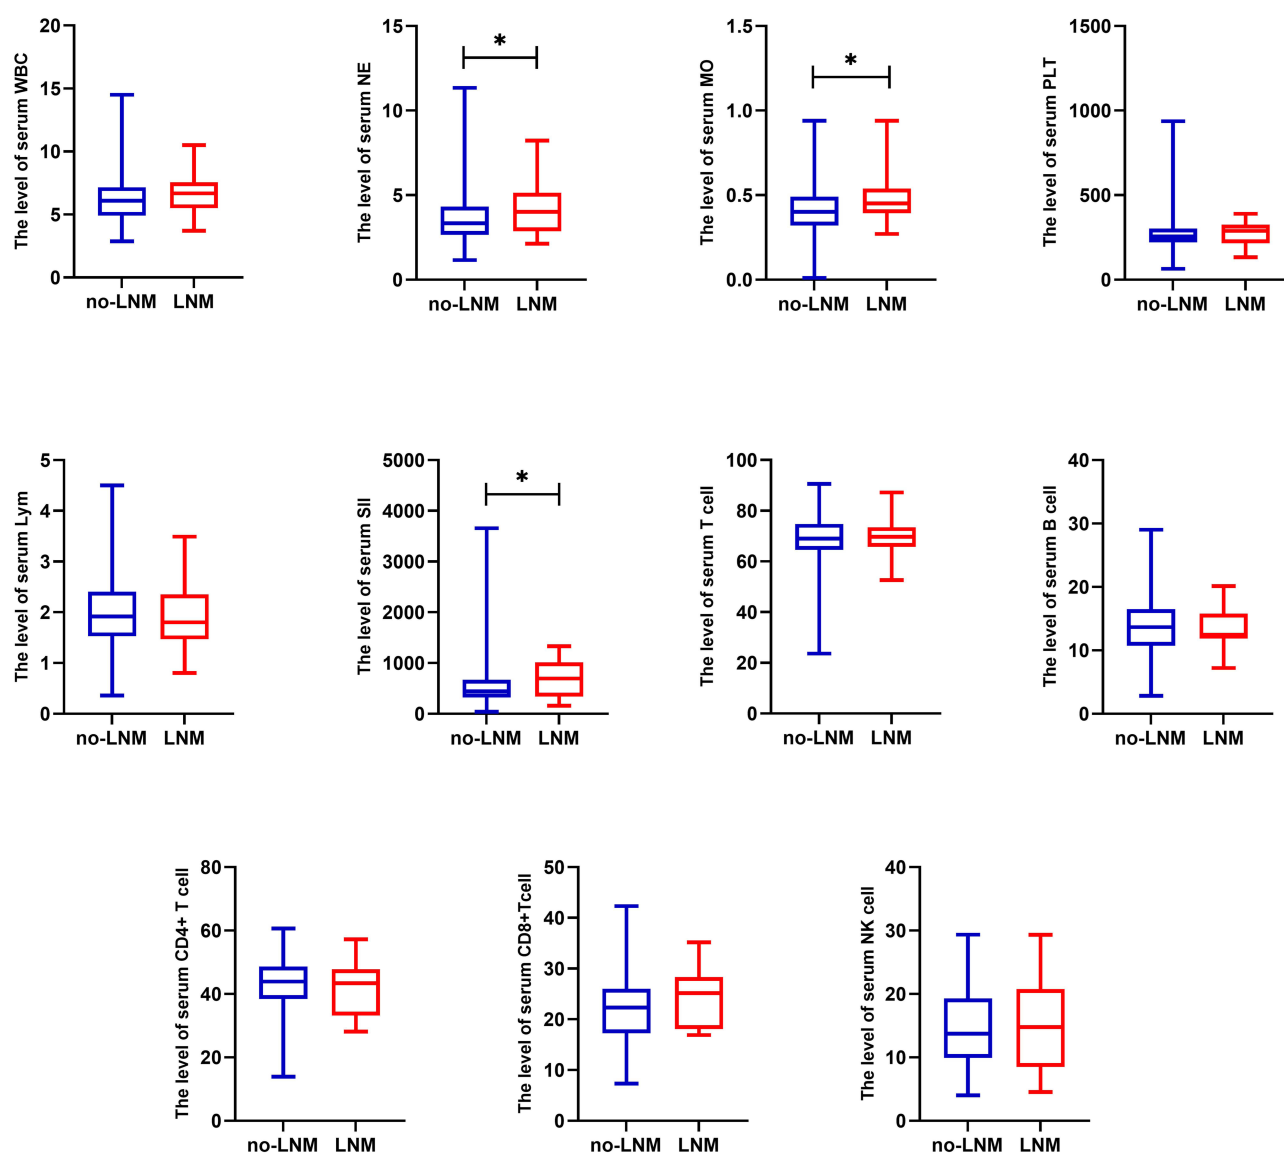

Figure 1 Characteristics of inflammatory immune cells in EC with LNM and no LNM.

patients. The results of the univariate logistic regression analysis showed that NE and MO counts, the SII, the levels of CA125, CA153, and CA199, and LVSI and ER expression were significantly associated with LNM (all $P < 0.05$, Figure 3A). Then, significant factors from the univariate analysis were included in the multivariate analysis. The results showed that the SII, CA125, CA153 and LVSI were independent risk factors for LNM (all $P < 0.05$, Figure 3B). The significant independent predictors identified in the logistic regression analysis were used to construct a nomogram for LNM to provide a method for quantitative prediction (Figure 4A). Calibration plots and ROC curves were used to assess the predictive accuracy of the nomogram. The calibration plots graphically showed good consistency between the actual observations and the predicted probabilities in the prediction of LNM, with Hosmer-Lemeshow $P=0.288$ (Figure 4B). The ROC curve analysis showed that compared with a single index, the combination of the SII, CA25, CA153 and LVSI could significantly improve the efficiency of diagnosing LNM in EC patients ($AUC=0.865$, $P < 0.001$, Figure 4B).

Correlations Between Clinicopathological Features and the SII

The SII was significantly associated with age, menopause, FIGO stage, and LNM (all $P < 0.05$, Table 2). To further

explore the clinical application value of the SII, we analyzed EC patients according to age and menopause. The results showed that the SII was closely related to pathological grade and MI in young premenopausal EC patients (all $P < 0.05$, Table 3). In EC patients age ≥ 55 years or with postmenopausal EC, the SII was associated with FIGO stage (all $P < 0.05$, Table 3). Further logistic regression analysis suggested that an elevated serum SII was an independent risk factor for MI and progression to a higher pathological grade in young premenopausal EC patients ($P < 0.05$, Figure 5A and B). In addition, an elevated SII was an independent risk factor for advanced EC progression in age ≥ 55 or postmenopausal EC patients ($P < 0.05$, Figure 5C).

Discussion

LNM is the main manifestation of EC metastasis and a key factor affecting the prognosis of patients with EC. Pelvic LNM is closely related to the prognosis of patients with EC, which is of great significance for the formulation of clinical treatment plans and prognosis monitoring of patients with EC.^{3,4} At present, there is no effective serum marker to predict LNM in EC patients. In previous studies, the systemic inflammatory response has been proven to be a factor in the poor prognosis of patients with various cancers.^{15–19} To investigate the simple and effective prognostic indexes used in the evaluation of the prognosis and guidance of clinical treatment of EC patients, many indexes based on

Figure 3 The logistic regression analyses. (A) Univariate logistic regression analyses for LNM. (B) Multivariate logistic regression analyses for LNM. P<0.05 indicates significant differences.

inflammation were studied and discussed, and this exploration focused on the value of the SII in the prediction of LNM in EC patients. Our study is the first to suggest that an elevated SII is an independent risk factor for LNM in patients with EC. In addition, the SII has different application value in pre- and postmenopausal EC patients. In premenopausal patients with EC, the SII can be used to assist in the assessment of deep MI and higher pathological grade. The results have implications for young women who want to keep their

uterus if they have a reproductive need. In postmenopausal EC patients, the SII was more closely associated with FIGO stage. An elevated SII was an independent risk factor for advanced EC in postmenopausal patients.

The inflammatory immune microenvironment plays an important role in tumorigenesis, development and metastasis.²⁰ Changes in the inflammatory tumor microenvironment contribute to the acquisition of malignant characteristics such as cancer cell proliferation,

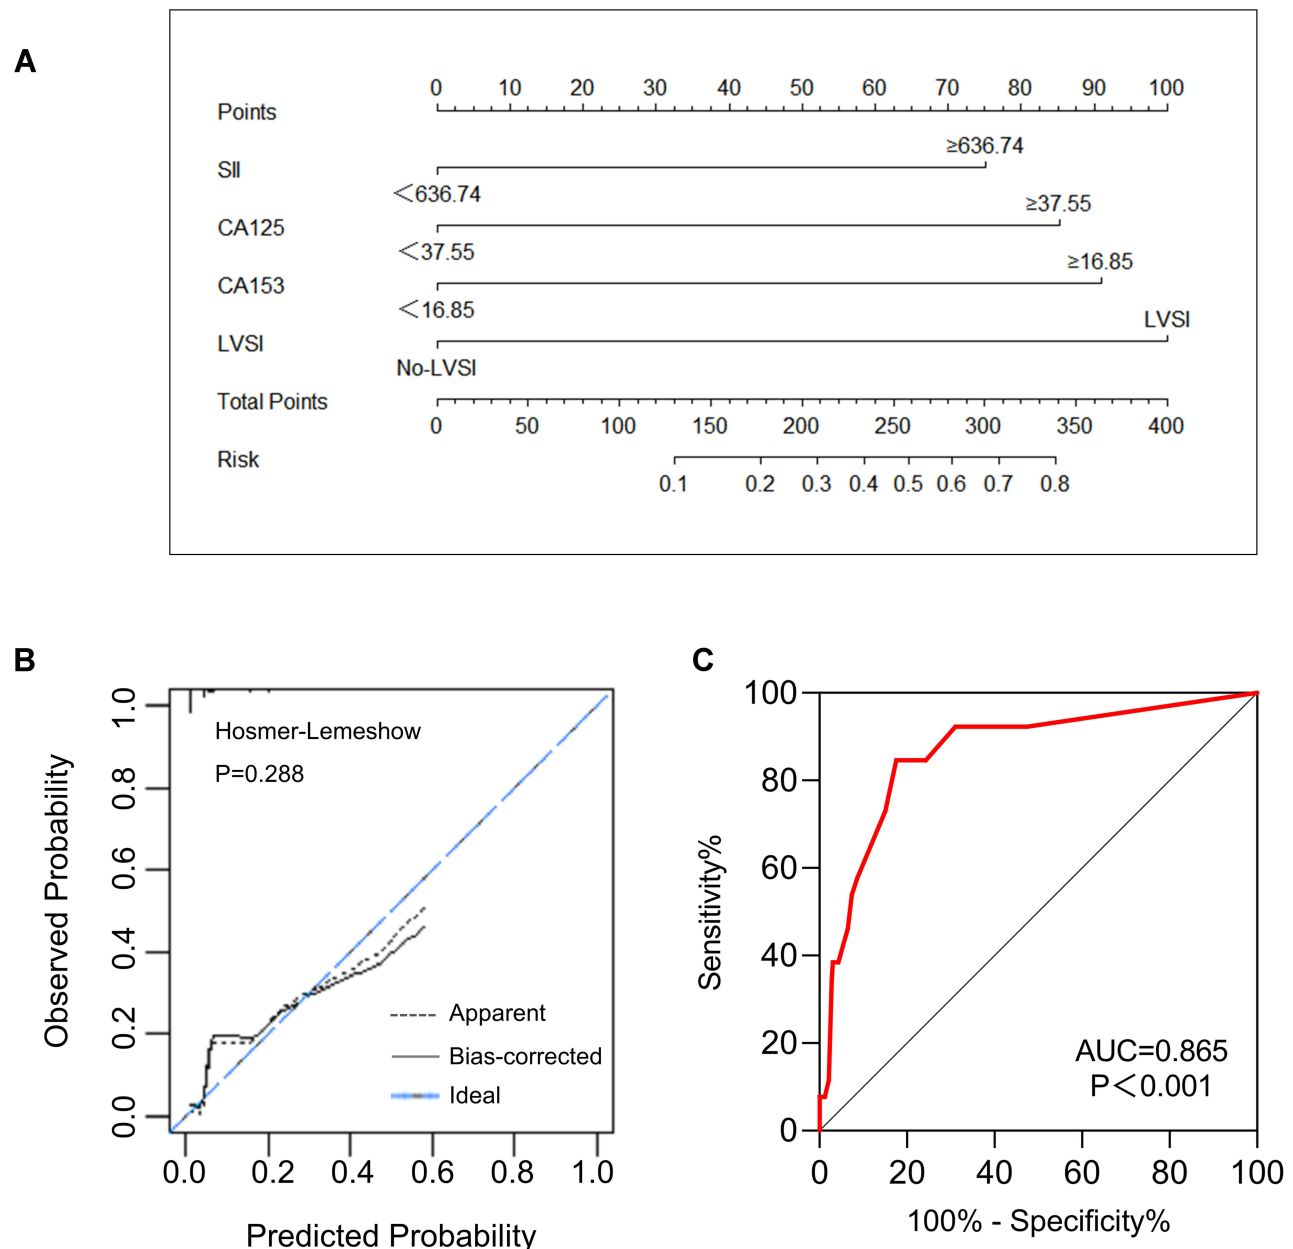

Figure 4 (A) The nomogram for predicting LNM with SII, CA125, CA153, and LVSI. (B) The calibration plots for the nomogram. (C) The ROC curve for the nomogram.

aggressiveness, metastasis, angiogenesis, and immune escape.^{20,21} Common inflammatory cells in peripheral blood include WBCs, Lym, NEs, MOs and PLTs. The relationship between systemic inflammatory markers and tumors has become a current research hotspot.

Lym have an immune recognition function and are an important part of the immune response mechanism of the body. Lym are involved in the regulation of tumor immunity and play a role in killing tumor cells by establishing an immune barrier.^{22,23} A decrease in the Lym level means that the immune function of the body is weakened and the

antitumor immune ability is decreased, thus promoting the recurrence and metastasis of tumors.^{22,23} However, studies on Lym counts in EC patients are limited. Some studies have shown that the Lym count is associated with the prognosis of EC.²⁴ In contrast, some studies suggest that the Lym count does not play a significant role in EC prognosis assessment.²⁵ In our study, there was no significant difference in the Lym counts among the EC patients with or without LNM. The differences in these results may be due to population differences or individual Lym counts that may be greatly influenced by changes in the body environment.

NEs are effector cells of the acute inflammatory response and play a major role in the clearance of extra-cellular pathogens. These cells are involved in the activation, regulation and effector functions of innate and adaptive immune cells.²⁶ Neutrophil elastase and vascular endothelial growth factor are closely related to tumor growth and metastasis.²⁶ Moreover, when systemic inflammation occurs in the body, in addition to an increase in the number of NEs and a decrease in the number of Lym, PLT levels increase, various chemokines activate PLTs, and activated PLTs release growth factors to support tumor growth and invasion.²⁷ Chen et al confirmed that a high PLT count was independently associated with poor RFS and OS in EC patients.²⁸ In addition, as an elevated SII reflects a status of elevated NE and PLT counts, we believe that factors that stimulate granulopoiesis and/or thrombopoiesis might also be involved in the mechanism responsible for the elevated SII in EC patients.

The SII is a novel index combining the counts of three inflammatory immune cells: Lym, NEs and PLTs. Studies have shown that the SII can predict the survival prognosis of patients with a variety of tumors.^{15–19} Screening and identifying high-risk patients have application value.

Holub et al¹⁹ suggested that the SII is associated with poorer outcomes in surgically staged I–III FIGO EC patients classified as high risk and treated with adjuvant EBRT and could be considered at cancer diagnosis. Matsubara et al¹⁸ confirmed that the SII is an independent prognostic factor in EC patients, allowing more precise survival estimation than PLR or NLR. However, the relationship between the SII and LNM in EC remains unclear. In our study, an elevated SII was confirmed to be an independent risk factor for LNM in patients with EC and could be used as a serum predictor of LNM in patients with EC, with good clinical application value. In addition, the SII was significantly associated with age and menopause in the correlation analysis. Therefore, we divided the EC patients into two groups according to age and menopause for subgroup analysis. The results showed that in young premenopausal women, the SII was closely associated with MI and a higher pathological grade in EC. For young premenopausal EC patients with reproductive needs, it is of great significance to evaluate the occurrence of muscular infiltration and pathological grading status. These findings have not been reported previously. We consider that future investigation of the underlying

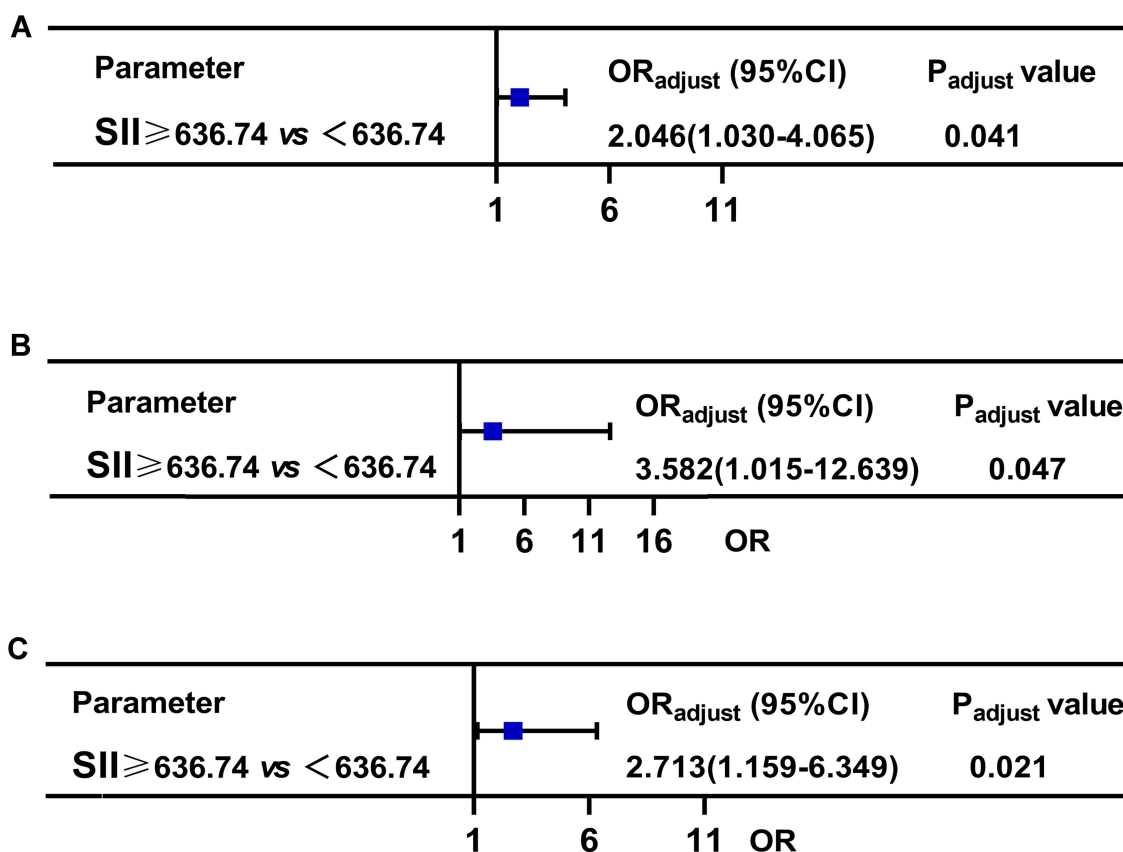

Figure 5 The logistic regression analyses. **(A)** Multivariate logistic regression analyses for myometrial invasion in premenopausal young EC. **(B)** Multivariate logistic regression analyses for histologic grade in premenopausal young EC. **(C)** Multivariate logistic regression analyses for FIGO stage in postmenopausal or age ≥ 55 EC.

Abbreviations: SII, Systemic Immune-Inflammatory Index; FIGO, International Federation of Gynecology and Obstetrics; OR_{adjust}, OR adjusted for age; P_{adjust}, P value adjusted for age.

causative mechanism of an elevated SII will aid in the development of novel effective treatments for EC.

LVSI is a high-risk factor for LNM in EC patients.²⁹ The presence of LVSI is associated with LNM, a critical factor with regard to staging, prognosis and treatment planning of clinically early-stage EC patients.³⁰ Consistent with previous studies, our results suggest that LVSI is an independent risk factor for LNM in EC patients. However, as LVSI is mostly diagnosed by pathology after surgery, it cannot be evaluated before surgery. Our study, combined with serum indicators, is easy to detect and can be used as an auxiliary indicator to determine LNM in patients with EC, with good clinical application value.

In addition, CA125 and CA153 were confirmed to be independent risk factors for LNM in EC patients in our study, which was consistent with previous studies.^{31–33} Moreover, our study combined the SII, CA125, CA153 and LVSI to significantly improve the efficacy of predicting LNM in EC patients.

There were also some limitations to this study. First, selection bias may exist, as this is a single-center retrospective study that represents the population only in some regions of China. Future studies should include a large, multicenter sample. Second, peripheral blood cell analysis results are easily affected by factors such as blood circulation capacity, infection, and nutritional status. Moreover, the treatment of patients after surgical resection has some heterogeneity, leading to different clinical outcomes.

In conclusion, the results of our study confirm that an elevated SII is an independent risk factor for LNM in patients with EC. In addition, the SII has different clinical application value in EC patients according to age and menopausal status. Notably, the SII can be used as a predictor of muscle invasion and a higher pathological grade in young premenopausal EC patients.

Data Sharing Statement

The datasets generated and/or analyzed during the current study are available from the corresponding author on reasonable request.

Ethical Approval

This study was approved by the ethical committee of the Department of Gynecology of Fujian Provincial Maternity and Children's Hospital. The study complied with the Declaration of Helsinki.

Journal of Inflammation Research

Dovepress

Publish your work in this journal

The Journal of Inflammation Research is an international, peer-reviewed open-access journal that welcomes laboratory and clinical findings on the molecular basis, cell biology and pharmacology of inflammation including original research, reviews, symposium reports, hypothesis formation and commentaries on: acute/chronic inflammation; mediators of inflammation; cellular processes; molecular

mechanisms; pharmacology and novel anti-inflammatory drugs; clinical conditions involving inflammation. The manuscript management system is completely online and includes a very quick and fair peer-review system. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/journal-of-inflammation-research-journal>
