Purpose: To provide data on acute and long-term outcomes from pulmonary vein isolation with the pulmonary vein ablation catheter (PVAC) in patients with paroxysmal or persistent atrial fibrillation (AF).

Methods: This was a single-center, retrospective, nonrandomized, case control study. Patients with documented symptomatic paroxysmal or persistent AF were treated with PVAC or with point-by-point radiofrequency ablation guided by the NavX™ mapping system. All follow-up visits were conducted in our center at 1 month, 3 months, and 6 months, and then at 6-month intervals. Electrocardiography and 24-hour Holter monitoring were performed at each follow-up visit. The endpoints included procedure times, acute and 24-month outcomes, and complications.

Results: Of the 539 patients that were enrolled consecutively, 388 were ablated using PVAC and 151 using radiofrequency ablation. More patients with paroxysmal AF were treated with PVAC than with radiofrequency ablation. Acute success rates were >99% with both methods. Procedure duration and fluoroscopy times were significantly ($P<0.001$) shorter with PVAC than with point-by-point ablation. Rates of freedom from AF at all follow-up times available (up to 24 months) were significantly higher after PVAC ablation than with radiofrequency ablation (64.2% versus 48.2% at 24 months). With both ablation strategies, the rates of freedom from AF were higher in patients with paroxysmal AF than for persistent AF. Two posterior cerebral infarcts occurred in the PVAC group within 2 days of the procedure. No phrenic nerve injuries and no esophageal injuries were recorded. Data on embolic lesions were not collected.

Conclusion: PVAC ablation achieved higher 24-month rates of AF-free survival than conventional radiofrequency ablation. Procedure and fluoroscopy times were shorter with PVAC, although the differences between groups may have influenced the results.

Keywords: arrhythmia, atrial fibrillation, catheter ablation, pulmonary vein isolation, long-term follow-up, safety

Introduction

Atrial fibrillation (AF) is the most common cardiac arrhythmia in the general population.^{1,2} Estimated prevalence rates range between 1% and 2%, and true rates including asymptomatic AF may be significantly higher than the diagnosed rates.³ Circumferential pulmonary vein isolation (PVI) by irrigated point-by-point radiofrequency (RF) catheter ablation is a highly effective intervention against AF at the paroxysmal AF (PAF) stage. In persistent AF, additional linear ablations are often needed to increase success rates and to improve long-term outcomes.⁴

The pulmonary vein ablation catheter (PVAC)^{5,6} was developed as an alternative to conventional RF ablation – in particular, to overcome the recognized difficulties in generating contiguous transmural lesions with a single-point catheter. PVAC is based on anatomically designed catheters that enable circumferential ablation across a wide area, encircling the pulmonary vein (PV) antrum without the use of additional sophisticated mapping systems to guide ablation.

Available data comparing PVAC with irrigated point-by-point RF ablation suggest similar acute and short-term ablation success rates with both methods in patients with paroxysmal or persistent AF.^{5,7,8} However, the number of patients in published reports remains limited; there are few publications that outline experiences with PVAC under conditions of actual care, and comparisons with Carto® (Biosense Webster, Inc., Diamond Bar, CA, USA) and NavX™ (St Jude Medical, Inc., Saint Paul, MN, USA) are rare.^{9,10} In addition, there are few data available on the technology in patients with persistent or long-lasting AF. As with all recent technologies, more studies with long-term follow-up are needed.

The aim of the present study was to perform a retrospective analysis of AF ablation procedures with PVAC and conventional RF catheter ablation for PVI in patients with paroxysmal or persistent AF treated at our center between 2005 and 2011. The endpoints included acute and long-term outcomes (over >24 months), procedure times, and complications.

Methods

Study design

This was a retrospective, nonrandomized, case controlled study conducted in patients treated at our center between October 1, 2005 and December 31, 2011. The study was conducted in compliance with Good Clinical Practice guidelines and consistent with the Declaration of Helsinki.¹¹ All patients provided written, informed consent.

Patients had documented symptomatic paroxysmal or persistent AF with a history of failed treatment with ≥ 1 antiarrhythmic drug. None of the patients had undergone ablation for AF previously. All patients were screened with cardiac computed tomography (CT) to define the PV anatomy and to exclude the contraindications for ablation used at our center (a significant reduction in left/right ventricular systolic function, coronary heart disease, tachycardia-mediated cardiomyopathy, left atrial [LA] appendage thrombus, atrial enlargement >55 mm, or mitral insufficiency higher than grade 2). Patients were enrolled consecutively and were treated with

PVAC or conventional point-by-point ablation guided by the NavX mapping with the choice in each individual case at the discretion of the treating physician. There was no protocol that detailed standardized recommendations.

PVAC

The PVAC is an over-the-wire, circular, decapolar mapping and RF ablation catheter with a 25 mm diameter array at the distal tip. The diameter of the electrode array can be increased or decreased by engaging the array against anatomical structures, allowing for the creation of circular lesions around up to ten electrodes. Rotating the catheter shaft changes the diameter of the array, enabling ablation around smaller or larger veins. PVAC is employed together with a multichannel RF generator (GENius; Medtronic, Minneapolis, MN, USA) that enables synchronous uni- and bipolar RF energy delivery to any combination of PVAC electrodes.^{7,8} Mapping is performed by bipolar recordings through adjacent electrode pairs.

PVAC procedures

Oral anticoagulation was stopped before the procedures, and low-molecular weight heparin was used as a bridging anticoagulant. Intravenous heparin was used during the procedures to maintain an activated clotting time >300 seconds. After a single transseptal puncture, a fixed-curve, long 10 F sheath (Frontier Advance; Medtronic) was inserted into the LA. Angiography with selective contrast injection was performed to visualize the PV ostia.

The PVAC was inserted via the 10 F sheath. A 0.032 inch guide wire was placed inside the PV and was used to advance the catheter until it was wedged within the antrum, proximal to the ostium, to record local electrical activity at the veno-atrial junction prior to RF energy application. When the PV fit the diameter of the PVAC, the catheter was pushed against the PV antrum. In cases where a large PV ostium or a common ostium was noted, the PVAC was sequentially repositioned around the ostium of the PV or at the antral site of the common ostium to achieve PVI. Prior to ablation, electrical signals from all veno-atrial junctions were recorded using the PVAC to provide reference PVAC signals for the recordings made after every RF application. RF energy was delivered with the GENius generator. Energy was applied in a 4:1 bipolar/unipolar ratio initially, titrated to 2:1 as necessary if the PV potentials were not eliminated. Energy was delivered in a temperature-controlled, power-limited manner with maximally 10 W per electrode. Each energy application lasted for 60 seconds with a temperature target of 60°C for each electrode in the selected

pairs. If the temperature did not rise above 50°C within 15 seconds, or in case of power oscillation, the application was discontinued and the position improved.

All PVs were mapped with the PVAC 15–30 minutes post-ablation. PV isolation was defined as entrance and exit blocks (Figure 1). If PVs appeared to be incompletely isolated, additional RF applications were delivered until PV isolation was achieved based on PVAC signals. Patients who failed repeated ablation attempts (as defined by the treating physician) were put on antiarrhythmic drug regimens.

Point-by point ablation

Access to the LA was obtained with a single transeptal puncture. The three-dimensional (3D)-geometry of the LA was reconstructed using the EnSite™ NavX™ and NavX™ Fusion systems (St Jude Medical, Inc.). RF energy was applied to encircle the right and left PV guided by the NavX system using an externally-irrigated-tip catheter (Celsius® ThermoCool®; Biosense Webster, Inc.) and an EP-Shuttle

generator (Stockert; Biosense Webster, Inc.). The applied power ranged from 20 W to a maximum of 35 W, to target a maximal temperature of 45°C.

Circumferential ablation was performed on the posterior wall (>1 cm) and on the anterior wall, >5 mm away from the predefined PV ostia. In patients with persistent AF, additional linear lesions at the LA roof and mitral isthmus were generated to eliminate additional arrhythmogenic substrate and to prevent large atrial re-entrant circuits. The diameter of the circumferential catheter was adjusted to the diameter of the PV antrum. Successful isolation of all four PVs was confirmed as an entrance and exit block. A complete block was defined as the presence of double potentials along the entire ablation line.¹² Other details were the same as in the PVAC group.

Follow-up and outcomes

Patients were discharged from hospital 1–2 days after the procedure. Oral anticoagulation was administered to all patients for 3 months after the ablation procedure, targeting an internal

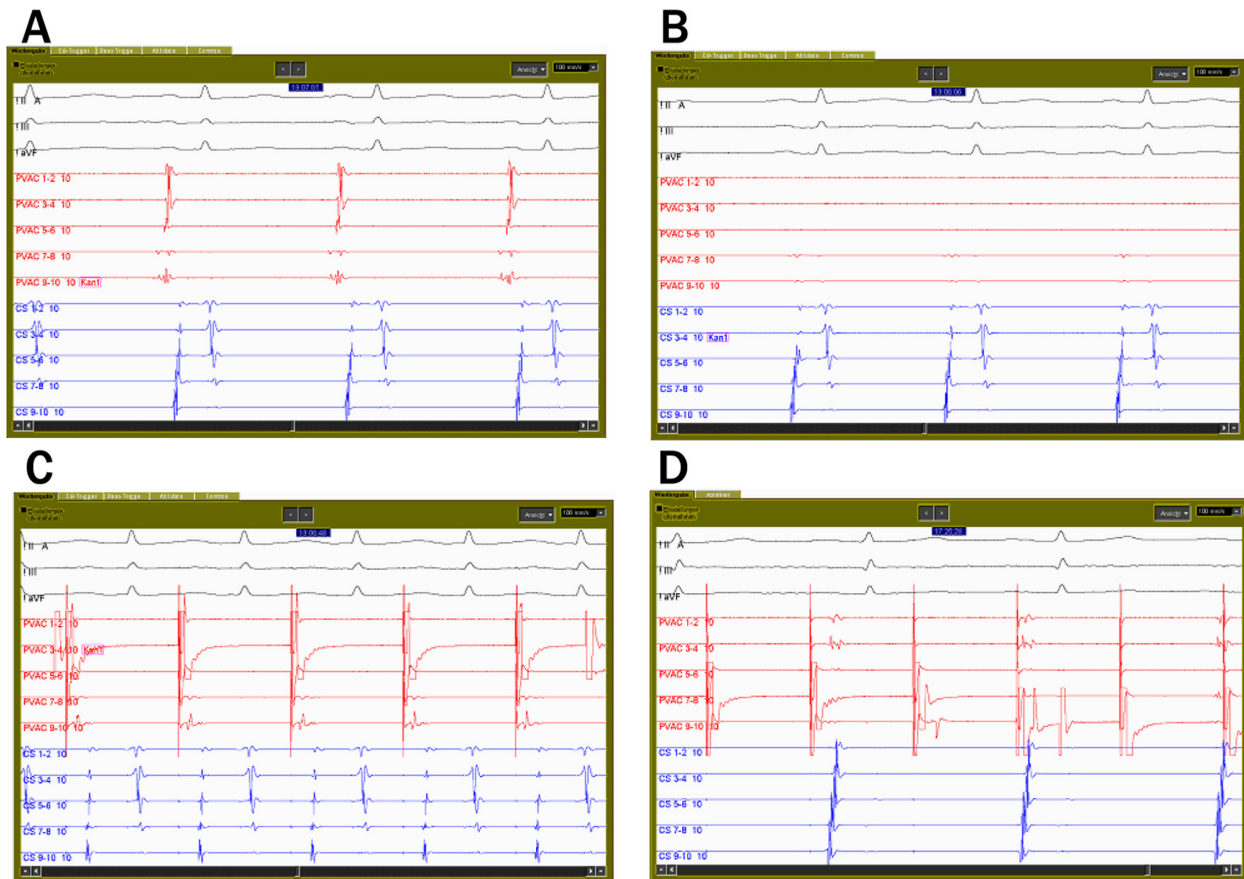

Figure 1 Pulmonary vein ablation catheter electrograms from the left inferior pulmonary vein.

normalized ratio of 2.0–3.0. All follow-up visits were held in our center, and they were scheduled at 1 month, 3 months, and 6 months, as well as at 6-monthly intervals thereafter. Electrocardiography and 24-hour Holter monitoring were performed to confirm sinus rhythm at each follow-up visit, consistent with the recommendations of the Heart Rhythm Society/European Heart Rhythm Association/European Cardiac Arrhythmia Society (HRS/EHRA/ECAS) expert Consensus Statement on catheter and surgical ablation of AF.¹³ In the PVAC group, redo ablation procedures were performed with PVAC. In the NavX group, and if a second redo procedure was necessary in both groups, point-by-point ablation and NavX was used. At the 12-month follow-up, a 4-day Holter was performed in addition to the 24-hour Holter monitoring in all patients. No event recorder was used. Antiarrhythmic medication was prescribed for patients with electrocardiography- or 4-day Holter-documented AF recurrence.

The primary outcome was maintained sinus rhythm with freedom from AF recurrence. This was defined as a sinus rhythm with no AF of >30 seconds duration documented on a 24-hour Holter, and no documented AF during the intervals between follow-up visits. Secondary outcomes were procedure times, number of RF applications, and peri- and post-procedural complications.

The majority of the procedures were conducted before concerns about the potential for subclinical embolic events during PVI were published.¹⁴ No brain magnetic resonance imaging (MRI) was carried out in our patients, but thromboembolic events were recorded in the safety analysis.

Statistical procedures

SPSS for Microsoft Windows (IBM Corporation, Armonk, NY, USA) was used for the statistical analyses. Continuous variables are expressed as means \pm standard deviations. Categorical variables are presented as percentages. Comparisons between the two groups were made with the χ^2 test and the Student–Newman–Keuls test, as appropriate. A univariate logistic regression analysis was performed for the variables listed in Table 3. A multivariate logistic regression analysis was conducted, and it included the following variables: type of ablation; type of AF; atrial size; ejection fraction; and number of ablations. For all analyses, a *P*-value <0.05 was considered statistically significant.

Results

A total of 539 patients were enrolled consecutively. The PVAC catheter was used in 388 patients and point-by-point ablation with NavX mapping in 151 patients – 68 of whom

were treated utilizing the NavX Fusion system with integrated CT. Baseline characteristics are shown in Table 1. Patients treated with PVAC were, on average, older (average 61 years in the PVAC group versus 58 years in the NavX group), and they exhibited a greater prevalence of mitral insufficiency and a greater prevalence of PAF (80% in the PLAC group and 54% in the NavX group, respectively). There were no differences between the groups in terms of sex distribution, duration of AF, or LA size.

Procedures

On average, 17.5 \pm 4.5 applications were needed in the PVAC group and 53.7 \pm 22.6 applications were needed in the NavX-guided ablation group (Table 2). In the NavX group, roof-line and LA isthmus ablation was performed in 54 patients; a box lesion and LA isthmus ablation were necessary in 81 patients. Acute success rates for PVI were >99%; only two right superior pulmonary veins and four right inferior pulmonary veins in the PVAC group could not be ablated due to their close proximity to the phrenic nerve. There were no differences in acute PVI success rates

Table 1 Baseline characteristics

Variable	NavX-guided ablation (n=151)	PVAC ablation (n=388)	P-value

Table 2 Procedural data

	NavX-guided ablation (n=151)	PVAC ablation (n=388)	P-value
Procedure time minute \pm SD	142.2 \pm 35.0	67.0 \pm 18.0	<0.001
Fluoroscopy time minute \pm SD	29.3 \pm 9.8	15.6 \pm 5.7	<0.001
Number of applications \pm SD	53.7 \pm 22.6	17.5 \pm 4.5	<0.0001
Energy applied W/second \pm SD	46.0 \pm 16.1	38.3 \pm 10.5	<0.001

Abbreviations: n, number; PVAC, pulmonary vein ablation catheter; SD, standard deviation.

between the methods employed. The total duration of the procedure was significantly ($P<0.01$) shorter with PVAC technology (67.0 \pm 18.0 minutes) than with point-by-point ablation (142.2 \pm 35.0 minutes). Differences were greatest for the ablation of PAF (67.4 \pm 18.2 minutes with PVAC versus 147.0 \pm 36.8 minutes with NavX), but a similar time advantage was observed for persistent AF (65.5 \pm 16.8 minutes with PVAC versus 136.5 \pm 31.9 minutes with NavX). Notably, average fluoroscopy time with PVAC (15.6 \pm 5.7 minutes) was almost half that with NavX-guided ablation (29.3 \pm 9.8 minutes; $P<0.001$ for the comparison).

Follow-up data for ≥ 1 month were available for all of the treated patients. In the NavX group, the mean follow-up was 51.9 \pm 13.4 months and 89 patients were followed for 60 months. In the PVAC group, the average duration of follow-up was 15.6 \pm 10.4 months and 161 patients were followed for 26 months.

Overall, redo ablation procedures in paroxysmal as well as persistent AF within 1 year of the initial procedure were necessary in 42 patients (10.7%) treated with PVAC ablation and in 23 patients (15.1%) treated with NavX-guided ablation, respectively. The differences were not significant. At 3 months, 6 months, and 12 months after PVAC ablation (including redo procedures), 70.0%, 67.9% and 64.0% of patients were free from AF; the percentages of patients free from AF after NavX-guided ablation were 45.0%, 37.8%, and 45.6% at the same time points, respectively ($P<0.005$ for all comparisons; Figure 2A). The percentages of patients free from AF were maintained at 24 months (Figure 2A). These differences in outcomes were less emphasized among patients with PAF (Figure 2B), but in patients with persistent or permanent AF, the rates of freedom from AF with PVAC were consistently around twice those with NavX-guided ablation (Figure 2C). Because of the low numbers of patients in the subgroups with persistent/permanent AF, standard deviations were large and the differences were not statistically significant.

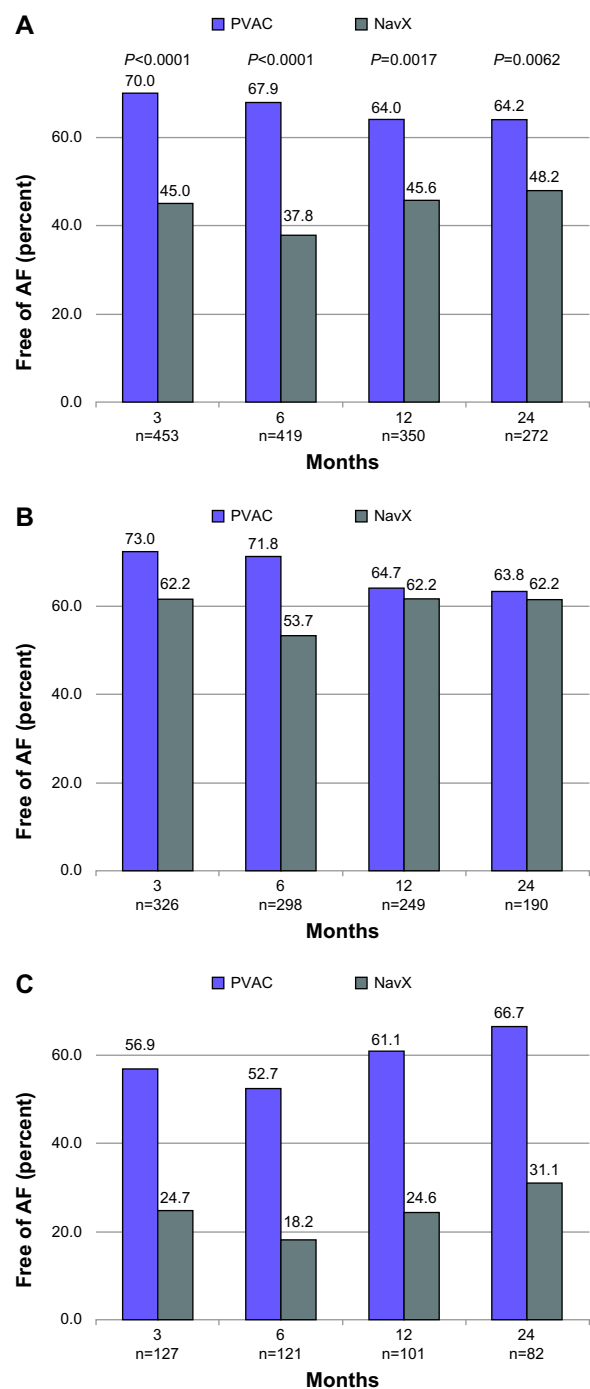

Figure 2 Percent of patients free from AF at different time points during follow-up. **Notes:** Blue bars indicate patients treated with the PVAC; grey bars are patients treated with NavX-guided point-by-point ablation. (A) All patients; (B) patients with paroxysmal AF; and (C) patients with persistent/long-lasting persistent AF. **Abbreviations:** PVAC, pulmonary vein ablation catheter; AF, atrial fibrillation; n, number.

Predictors of successful ablation

Predictors of outcomes were analyzed at 12 months for the entire patient collective. The improved outcomes with PVAC compared with NavX-guided ablation were confirmed ($P=0.017$), as were the higher rates of AF-free survival

post-ablation in patients with PAF when compared to those with persistent/long-lasting persistent AF ($P<0.0001$). A univariate regression analysis showed that the type of AF, ablation method, and the number and duration of ablations were significant predictors of long-term AF-free survival, together with ejection fraction (Table 3). The predictive value of the type of AF ($P=0.0002$) and the number of ablations ($P<0.00001$) were confirmed in a multivariate regression analysis.

Complications

There were no deaths. Two posterior cerebral infarcts occurred in the PVAC group within 2 days of the procedure. In both cases, patients recovered, and long-term neurocognitive performance was not affected. Three pericardial tamponades occurred with PVAC and four with NavX. In each group, there was one post-procedural femoral aneurysm that needed intervention. One case of pericardial effusion occurred in each group. No phrenic nerve injuries and no esophageal injuries were recorded.

In a separate analysis of a subgroup of the PVAC population, CT data from 49 patients and 192 PVs were analyzed for the presence of PV stenosis 6 months from the procedure. One mild case of PV stenosis (left superior pulmonary vein; a $<50\%$ reduction in PV diameter) was identified in these patients.

Discussion

The results presented here from a large patient cohort treated in our center under conditions of actual care showed that PVAC is associated with favorable rates of AF-free survival

over a mean follow-up of 26 months. Notably, the PVAC procedure was highly successful in long-lasting persistent AF, with a significantly greater percentage of freedom from AF at 24 months in PVAC-treated patients than in patients treated by point-by-point ablation. In addition, the data confirmed the short fluoroscopy and procedure times with PVAC that have been reported by other investigators in various study settings.^{9,10}

To our knowledge, the duration of follow-up in our cohort is the longest reported to date for PVAC, particularly in patients with persistent/long-lasting persistent AF. The rates of freedom from PAF after 12 months of follow-up were highly similar to those reported for the technology in a recent meta-analysis.¹⁵ Interestingly, the rates remained at similar levels throughout the rest of the follow-up, which indicates that most AF recurrences happen early – an observation that has been made earlier both for PVAC¹⁶ and for other ablation techniques.¹⁷ The phenomenon may be related to pathology rather than to the technology used. If patients at greatest risk of AF recurrence tend to experience the first occurrence within the first 12 months, then patients who remain AF-free for a year may have a different pathology, making them less likely to develop AF over longer periods of time. The underlying differences in pathology would warrant further research and thorough analyses of patients pre- and post-ablation.

As this was a nonrandomized observational study, direct comparisons between the two groups shall be made with some caution. Within the limitations of the study design, we note the significant differences in success rates between PVAC and point-to-point ablation. These differences were greatest in patients with persistent/long-lasting persistent AF. In this group, 12-month rates of AF-free survival after PVAC ablation were >15 percentage points higher than what two earlier studies have reported.^{18,19} It appears unlikely that underreporting of events during follow-up would be a reason for these remarkably high success rates, as long-term rates for our patients in the NavX group were not different from those in other studies. Some of the low rates observed with point-by-point ablation may be attributable to the mapping methods used to confirm PVI in the earlier cases, but this is unlikely to account for all of the differences between the systems. The number of patients with persistent/long-lasting persistent AF in our cohort was 82, which is more than twice the number in the studies cited. The greater rates of freedom from AF with PVAC than with point-by-point ablation in these patients is remarkable, and we can only speculate the reasons for these results. The depth of the lesions created with PVAC

Table 3 Univariate analysis of predictors of long-term freedom from ablation

Variable	Odds ratio	95% confidence interval	P-value
Age	0.9998	0.9809–1.0189	0.9795

Abbreviations: LA, left atrium; EF, ejection fraction; AF, atrial fibrillation.

can be influenced by the bipolar:unipolar ratio;²⁰ however, any explanation remains unproven at present, and we note that the total number of patients with persistent/long-lasting persistent AF treated with PVAC is still relatively small.

There were large and statistically significant differences between the groups in terms of the number of applications and the total procedure and fluoroscopy times, all of which were in favor of PVAC. While the differences in our center were greater than some others have reported,²¹ the finding of shorter times, especially with respect to fluoroscopy times associated with PVAC, is consistent with the findings from several other investigator teams in different study settings.^{9,10,19,22}

Differences between the groups at baseline may account for part of the differences observed during the study. However, when analyzed separately, procedure times with PVAC remained shorter for all types of AF. One reason for these short times is that no separate mapping catheters are needed when using PVAC. More patients had persistent/long-lasting persistent AF and more complex procedures were necessary in the group using point-by-point ablation. Persistent/long-lasting persistent AF typically needs additional linear

lesions to interrupt re-entrant wavelets, and often a roofline and a mitral line in addition to ensure long-term freedom of AF recurrences.⁴ Thus, the main factor is most likely the complexity of the point-by-point ablation procedure itself, even when using high-quality mapping systems. The rationale for the design of the anatomically designed catheter was to enable the generation of reliable contiguous transmural lesions over long distances. Our shorter procedure times corroborate the soundness of these considerations.

Comparing NavX with NavX Fusion (Figure 3), it is not clear that procedure and fluoroscopy times improved with the change from NavX to NavX Fusion in our experience. The integration of CT images into 3D mapping systems is intended to simplify the creation of lesions and to shorten procedure and fluoroscopy times. In part, the lack of differences may be due to the learning curve with the new CT-Fusion system,²³ although the integrated system reduced the number of applications without an obvious learning curve.

The safety profiles were favorable for both procedures. In particular, we found very low rates of PV stenosis, which was recently flagged as a possible complication of PVAC

Figure 3 Procedure and fluoroscopy times, and number of applications for ablation guided by NavX and NavX Fusion, as well as PVAC ablation, respectively.

Notes: Lines indicate SD. Differences were significant for all comparisons between PVAC and NavX or NavX Fusion. No significant differences were found between NavX and NavX Fusion.

Abbreviations: PVAC, pulmonary vein ablation catheter; SD, standard deviation.

ablation.²⁴ We did not systematically assess PV stenosis in all patients, but a retrospective analysis of 192 PVs showed only one mild case, corresponding to an incidence rate of 0.5% overall. This is considerably lower than the rate of 7%, as reported in 410 PVs in the study by von Bary et al.²⁴ Other investigators have reported no PV stenosis in smaller patient groups.^{10,21} Detailed imaging and anatomical analysis of the PV anatomy is clearly important in reducing the risk of complications. All patients in our center undergo CT/MRI scans as a matter of routine to define the PV anatomy before the ablation procedures – a procedure that may have contributed to the low rate of PV stenosis that was observed.

Recently, there have been concerns about the potential for subclinical intracranial embolic events during PVI that go unrecognized in everyday clinical practice, but that can be detected with brain MRI.¹⁴ Although no data on clinical thromboembolisms are available at present,²⁵ a greater potential for subclinical events with the PVAC catheter has been suggested, as compared with other RF ablation methods.^{22,26,27} PVAC relies on passive circulatory cooling from blood flow without active irrigation during “off-periods” of duty-cycled RF-current delivery, and it has been questioned whether thrombus formation and charring can be minimized routinely by relying on this mechanism with no irrigation.²⁸

In our retrospective analysis, thromboembolic events were recorded, but no MRI data on embolic lesions were available. There were two cases of cerebral infarcts among the 388 patients in the PVAC group within 2 days of the procedure. The relationship of these events to PVAC is unclear. Rates of around 1% neurologic events, including symptomatic transient ischemic attack/stroke, with duty-cycled RF ablation were recently reported in a large survey.²⁹ These rates are in the same range as those reported with conventional RF.^{30,31} Asymptomatic cerebral infarction rates of ~14% with irrigated-tip catheters have been reported.³² Recently, the multicenter Evaluation of the Incidence of Cerebral Lesions Post Pulmonary Vein Ablation Catheter (ERACE) study³³ showed that applying procedural changes to multielectrode radiofrequency ablation significantly reduced the incidence of asymptomatic cerebral emboli to 1.7%, which is as low as the reported rates of any technology. Multicenter studies such as the ongoing PRECISION GOLD trial (ClinicalTrials.gov identifier NCT01767558³⁴) comparing the long-term clinical safety of conventional and duty-cycled multipolar ablation will be needed to lay the issue to rest.

Limitations

This was a single-center retrospective study, and the individual physician’s experience and choice of ablation method

for individual patients may have influenced outcomes. The two treatment groups were not balanced for all variables at baseline, with a greater percentage of persistent/long-lasting persistent AF patients in the NavX group and higher rates of mitral insufficiency in the group treated with PVAC. Procedure times for PAF are typically shorter than for other forms, which would have favored the PVAC group for these outcomes. Mitral insufficiency is linked to increased risk of developing AF,³⁵ but it is difficult to say how such differences between the groups may have affected the outcomes.

The observational nature and consequential enrollment mean that the data represent a historical comparison, and that ablation procedures from the mid-2000s were included in the analysis. AF ablation methods and the operators’ experience have progressed with time. On the one hand, this is a weakness of the analysis, but on the other hand, it permits a view of the dynamic, real world of AF ablation, as performed over a long time period. The consequential enrollment may have affected the outcomes, but we believe the comparison retains validity. Over a study population of >500 patients and 6 years, initial learning curves will have mostly evened out for both techniques.

The follow-up time of 24 months does not quite meet the recent definition of >36 months for long-term freedom from AF³⁶ and it may have been too short to detect differences in long-time safety. However, in contrast to several other long-term studies, monitoring for AF after 1 year was no less thorough than during the first 12 months of follow-up. Moreover, the number of patients ablated with PVAC was an order of magnitude larger than in published randomized studies. Most follow-up visits utilized 24-hour Holter analyses, and the rates of PAF may be underestimated in our data.³⁷ Four-day Holter analyses at all time points might have increased detection rates. Finally, no specific safety studies were conducted, except for the subset of patients assessed for PV stenosis; subclinical embolic events were not monitored.

Conclusion

In this large cohort of patients treated as per clinical practice, PVAC ablation was associated with similar or superior long-term rates of AF-free survival compared with point-by-point ablation using conventional 3D mapping, and it was associated with significantly shorter procedure and fluoroscopy times. The safety profiles were favorable for both techniques. Data on embolic lesions were not collected, and this issue would need to be evaluated in separate studies.

Author contributions

All authors were involved in the ablation procedures and in the collection and analysis of data. SGS was responsible for the production of the manuscript. All authors contributed toward and approved the final draft.

Disclosure

The conduct of this study and the analysis of the data received no industry sponsorship. SGS has received research support from Ablation Frontiers and from Medtronic. The authors report no other conflicts of interest in this work.

Research Reports in Clinical Cardiology

Publish your work in this journal

Research Reports in Clinical Cardiology is an international, peer-reviewed, open access journal publishing original research, reports, editorials, reviews and commentaries on all areas of cardiology in the clinic and laboratory. The manuscript management system is completely online and includes a very quick and fair peer-review system.

Submit your manuscript here: <http://www.dovepress.com/research-reports-in-clinical-cardiology-journal>
