Purpose: Cardiorespiratory fitness (CRF) plays an essential role in health outcomes and quality of life. However, it is often not assessed nor estimated. Objective CRF assessment is costly, labour intensive and not widely available. Patient-reported outcome measures estimate CRF more cost-efficiently, but current questionnaires lack accuracy. The aim of this study is to develop a new self-reported questionnaire to estimate CRF.

Materials and Methods: The FitMáx©-questionnaire, consisting of only three questions assessing walking, stair climbing, and cycling capacity, was compared with the commonly used Duke Activity Status Index (DASI) and Veterans Specific Activity Questionnaire (VSAQ). These questionnaires were compared to peak oxygen uptake (VO_{2peak}) as measured with cardiopulmonary exercise testing. This study included 759 cardiac, pulmonary and oncologic patients and healthy persons aged 18–90.

Results: FitMáx© strongly correlated ($r = 0.94$ (0.92–0.95) SEE = $4.14 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) with measured VO_{2peak} . Bias between predicted and measured VO_{2peak} was -0.24 (-9.23 – 8.75 ; 95% limits of agreement) $\text{mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$. The FitMáx© scored superiorly on correlation and SEE compared with the DASI and VSAQ, $r = 0.75$ (0.68–0.80) SEE = $4.62 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ and $r = 0.87$ (0.83–0.90) SEE = $6.75 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$, respectively.

Conclusion: FitMáx© is a valid and accessible questionnaire to estimate CRF expressed as VO_{2peak} in clinical practice and shows substantial improvement compared to currently used questionnaires.

Keywords: cardiorespiratory fitness, sports medicine, rehabilitation, self-reported questionnaire, cardiopulmonary exercise testing

Introduction

Cardiorespiratory fitness (CRF), commonly defined as peak oxygen uptake (VO_{2peak}), is considered a vital sign, and holds an essential role in health outcomes and quality of life.^{1–3} Low CRF is associated with all-cause mortality.^{4–8} Enhancement of CRF leads to improvements in quality of life, and diminishes disease-related symptoms. Increasing VO_{2peak} by only $3.5 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ has been associated with a substantial 8–35% survival benefit in various populations.^{1,2,9} Given the importance of CRF in healthcare, and the fact that it is often amenable for improvement with exercise training, surprisingly it is often not assessed, nor estimated in most clinical situations.

Cardiorespiratory fitness can be objectively determined with cardiopulmonary exercise testing (CPET) in which the maximum amount of energy obtained by aerobic metabolism, or VO_{2peak} is assessed.^{10–13} Clinical CPET is increasingly

used to diagnose heart and lung diseases, since it also determines the cause(s) of exercise limitation. In many clinical cases, assessing and monitoring the exercise capacity of diseased patients (during treatment), is more important than to quantify the exact exercise limitation.¹⁴ Unfortunately, CPET is a costly, labour intensive, and not widely available test which leads to limited applicability.^{15,16}

An alternative way to assess CRF is use of self-reported questionnaires.¹⁴ The Duke Activity Status Index (DASI) and Veterans Specific Activity Questionnaire (VSAQ) are such questionnaires.^{17,18} The DASI, reached a correlation of $r=0.81$ with VO_{2peak} measured by CPET when taken by healthcare providers. In case of self-report however, DASI reached a correlation of $r=0.58$ in the same study. The standard error of the estimate (SEE) for the DASI was not reported.¹⁷ The VSAQ estimates the metabolic equivalent of a task (MET) and reached a correlation of $r=0.82$ with maximal MET achieved on CPET with a SEE of 1.43 MET ($5.0 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$). A major drawback of the VSAQ is the use of activities, such as basketball and skiing, which are not practiced globally.¹⁹

The capacity to perform daily activities like walking, stair climbing and bicycling are directly related to CRF.^{20–25} We developed the FitMáx© questionnaire, hereafter written as FitMáx, based upon these three activities to give a more accurate estimate of CRF, which is widely applicable in healthy persons and patients. The aim of this study is to validate the FitMáx as self-reported questionnaire to estimate CRF.

Materials and Methods

Setting

Data was collected prospectively from March 2018 until March 2020 in Máxima Medical Center (Máxima MC). This is a large Dutch non-academic teaching hospital with expertise in sports medicine and exercise physiology embedded in healthcare for cardiac, pulmonary and oncologic patients.^{26–29} Approximately 20 CPETs are performed every week for diagnostic or scientific purposes, and as part of (p)rehabilitation programmes. The current study complied with the Declaration of Helsinki and the authorized Medical Research Ethics Committee of Máxima MC issued a “non-WMO acknowledgement” (reference number N18.051).³⁰ The study was registered as NL8568 in the Netherlands Trial Register.

Study Population

Before data collection started, the FitMáx was tested and improved in a pilot study ($n=20$) via cognitive walkthrough. After this pilot study, minor adjustments were made and FitMáx was applied as self-reported questionnaire in the current study. Subjects aged ≥ 18 years, scheduled for CPET for Medical reasons or as part of a health check, were asked to participate on the day of the appointment prior to CPET. They received the study information letter, informed consent form and the FitMáx, VSAQ and DASI questionnaires. Since CRF can change over time, we have chosen to include subjects in the current study only if documents were completed within 6 weeks (<42 days) prior to or after performing CPET. Maximal exercise effort was considered to be achieved if one of the following criteria was met i) a breathing reserve $<15\%$ ($\text{Breathing reserve} = 100 - \left(\frac{\text{Maximal Ventilation}}{\text{FEV}_{1\ast 40}} \right) * 100$) ii) percentage of age related predicted maximal heart rate and age related Respiratory Exchange Ratio (RER) or iii) arterialized lactate level at maximal exercise $>4 \text{ mmol/L}$.^{10,31–34} Subjects were excluded when CPET was terminated submaximal by the physician due to eg uncontrolled arrhythmia or syncope, or if the FitMáx was incomplete. All participants have given written informed consent to inclusion of CPET and questionnaire data, which were fully anonymized.

Cardiopulmonary Exercise Testing

In this study cycle ergometer CPET was used to measure VO_{2peak} , which was defined as the averaged peak oxygen uptake in the last 30 seconds of CPET. The VO_{2peak} is often used interchangeably with maximum oxygen uptake (VO_{2max}), however to determine VO_{2max} , a plateau in VO_2 uptake despite increasing work load is necessary.³⁵ In clinical practice, this plateau is often not reached, which makes VO_{2peak} the preferred measure to express CRF.^{36,37} According to previous studies, cycle ergometer CPET is likely to underestimate VO_{2peak} compared to treadmill CPET.^{38,39} However, for safety concerns, to prevent measurement errors and because of the clinical infrastructure in the Máxima MC, we used cycle ergometer CPET as gold standard. All CPETs were supervised by sports physicians

or a human movement scientist, and conducted according to international standards.^{40–42} Prior to CPET, maximum attainable workload (in Watts) was estimated based on patient characteristics and subjective physical exercise capacity. Based on estimated maximum workload, a ramp protocol was used in which the subject was expected to reach maximum load within approximately 8–12 minutes.^{41,42} The person who supervised CPET was blinded for the results of the questionnaires which, if not blinded, could have biased the choice of exercise protocol. The tests were performed in a temperature-humidity controlled room. A 12-lead electrocardiogram was continuously recorded during rest, warm-up, exercise, and at least three minutes after maximal exercise (suction electrode KISS, GE Healthcare, Chicago, USA or Custo, CustoMed, GmbH, Ottobrunn, Germany). Gas exchange variables were measured breath-by-breath (Vyntus CPX, CareFusion, Hochberg, Germany or MetaLyzer 3B, Cortex, Leipzig, Germany). The metabolic cart was calibrated prior to testing by using a known gas concentration and automatic volume calibration.

Questionnaires

The FitMáx consists of three single-answer questions about the maximum capacity of daily life activities that are all frequently performed by the general Dutch population. A strength of this questionnaire is the use of three different activities in increasing intensity. This enables subjects to estimate their capacity on each activity separately, instead of using several activities in one question. Maximum walking capacity was chosen as a measure of CRF, since the distance walked during a six-minute walk test is strongly associated with VO_{2peak} in patients with severely reduced functional capacity.^{20,21} Maximum stair climbing capacity was chosen because previous studies indicate that the risk of perioperative pulmonary complications can be estimated with a stair climbing test.^{22–24} Lastly, maximum cycling capacity was used, since Dutch people often cycle in daily life and exercise testing is often performed on cycle ergometers to measure CRF.²⁵ We tried to draft distinguishable answer options that are unequivocal. The final FitMáx consists of a 1–14 scale for walking, 1–11 scale for stair climbing and 1–12 scale for cycling. The Dutch version of the FitMáx was translated into English, using forward backward translation according to the procedure described in the guidelines for cross-cultural adaptation.⁴³ The FitMáx is available in the [Supplementary File](#).

To assess the ability of subjects to complete the FitMáx, three extra questions with a scale 1–10 were used for walking, stair climbing and cycling capacity separately, in which 1 indicates “I cannot estimate properly” and 10 indicates “I can estimate properly”. These questions were added in a later phase of the study, and therefore results of $n=243$ participants are described.

Beside the FitMáx, subjects were asked to complete the VSAQ from the beginning of the study. The VSAQ was developed to estimate the maximal MET value in American veterans, which was then used in a formula to estimate the CRF expressed in VO_{2peak} .¹⁸ To expand the comparison with other physical fitness questionnaires, we also added the DASI to the validation study in April 2019. The DASI was developed to estimate aerobic capacity in cardiovascular patients and used to monitor rehabilitation progress.¹⁷ To enable direct comparison, results of all questionnaires were converted into VO_{2peak} in $mL \cdot kg^{-1} \cdot min^{-1}$, following the guidelines of these questionnaires.^{17,18}

Statistical Analysis

To evaluate the criterion validity of the FitMáx, cycle ergometer CPET was used as gold standard measure for CRF. Additionally, FitMáx was compared with DASI and VSAQ in the same population to evaluate the construct validity. To determine the internal consistency of the FitMáx we calculated the Cronbach’s Alpha.⁴⁴ Normality of the study data was assessed by visually evaluating histograms and calculation of skewness and kurtosis values.⁴⁵ Descriptive statistics for subjects’ characteristics are reported as mean and SD in case of normal distribution, and median and interquartile range (IQR) otherwise. For continuous variables, unpaired Student’s t-tests were used to evaluate differences between groups. If the assumption of a normal distribution was not met, the Wilcoxon rank sum test was used instead. The Chi-squared test was used for categorical variables.

For the estimation of CRF via the FitMáx scores, linear regression was chosen after exploratory data analysis. The steps of the FitMáx are ordered by definition. For the analysis, each step of the FitMáx was replaced by the mean VO_{2peak} of all values from subjects’ self-reported scores. These values were then used as regression variable in the model, together with significantly associated dependent variables. To avoid overfitting, we used the sample function in R to

randomly create two subgroups: 70% of the subjects as training set and the remaining 30% as testing set.⁴⁶ The training set was used to select the best-fitting linear regression model. We used stepwise regression to retain the variables that are most relevant for the prediction of CRF. We performed stepwise selection with 10-fold cross-validation with 100 repeats, retaining 20% of the data at each loop for validation. The residuals of the chosen model were examined on bias and heteroscedasticity (studentized Breusch-Pagan (Koenker-Bassett) test).^{47,48}

The final model was cross-validated on the testing set. Since no outliers were identified, the Pearson correlation coefficient (r) was used to evaluate the linear relationship between measured $\text{VO}_{2\text{peak}}$ and $\text{VO}_{2\text{peak}}$ estimated by FitMáx, VSAQ and DASI.⁴⁹ Additionally, the coefficient of determination (R^2) and SEE were calculated. While the correlation is not able to assess absolute agreement, the Intraclass Correlation Coefficient (ICC) was calculated.⁵⁰ Bland Altman plots were used to determine whether mean differences between estimated and measured $\text{VO}_{2\text{peak}}$, with corresponding limits of agreement (LoA), are dependent on the size of the measured $\text{VO}_{2\text{peak}}$ values.

The same methods were used to estimate the $\text{VO}_{2\text{peak}}$ from the three FitMáx questions separately, and also from the FitMáx with walking and stair climbing only. All computations were implemented in R (R-version 4.0).⁴⁶ A p-value of <0.05 was considered statistically significant.

Results

A total of 759 subjects (560 men and 199 women) who performed CPET and completed the FitMáx were included for analysis (see Figure 1). From the study population, 159 participants performed CPET as part of a health check and 600 participants for medical reasons. Since the DASI was added in a later phase of the study, it was received by 581 subjects, and completed by 517 subjects. The training set consisted of 531 subjects and the testing set of 228 subjects.

In the testing set, subjects' age ranged from 19–90 years with a $\text{VO}_{2\text{peak}}$ from 9.6–71.4 $\text{mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$, whereas in the training group the subjects' age ranged from 18–88 years with a $\text{VO}_{2\text{peak}}$ from 7.5–67.2 $\text{mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$. Variables relevant to interpret CPET results include height, bodyweight, lung function, Global Initiative for Chronic Obstructive

Figure 1 Flow diagram of participant selection. * Subjects with evidently submaximal performance on the CPET (ie not achieving volitional maximal effort), due to medical contraindications for maximal testing or measurement errors; ** Medical reasons were restrictions given by cardiologist and use of stair lift; *** eg never cycled before, use of electric bike.

Abbreviations: Walk, maximum walking capacity score of the FitMáx (1–14); stair climbing, maximum stair climbing capacity score of the FitMáx (1–11); cycling, maximum cycling capacity score of the FitMáx (1–12).

was not rejected by the studentized Breusch-Pagan (Koenker-Basset) test (p -value=0.76). The Cronbach's Alpha of the three FitMáx questions was 0.93 (0.93–0.94) in the total study sample.

Validation Prediction Model

Correlation of $\text{VO}_{2\text{peak}}$ estimated by FitMáx with measured $\text{VO}_{2\text{peak}}$ was higher $r=0.94$ (0.92–0.95) than the correlation of DASI $r=0.75$ (0.68–0.80) and VSAQ $r=0.87$ (0.83–0.90) (Figure 2A–C). Moreover, SEE and bias with LoA were smaller for the FitMáx and the R^2 and ICC were higher compared to the same values for DASI and VSAQ corrected for the smaller complete subset of the DASI (Table 3). Bias of the FitMáx was $-0.24 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$, which is smaller than the DASI ($3.32 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$) and VSAQ ($3.44 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$). Also, results of predicting $\text{VO}_{2\text{peak}}$ with the three FitMáx questions separately, and the combination of the walking and stair climbing capacity are presented in Table 3. The estimated $\text{VO}_{2\text{peak}}$ based on walking and stair climbing capacity reached a correlation of $r=0.90$ (0.88–0.92) with $\text{VO}_{2\text{peak}}$ measured by CPET. Although the values of correlation are comparable, SEE and LoA of the FitMáx including all three questions are smaller than the combination of walking and stair climbing only.

Bland Altman analysis shows the agreement between measured and estimated $\text{VO}_{2\text{peak}}$ by the FitMáx (LoA -9.23 – 8.75) to be independent of the $\text{VO}_{2\text{peak}}$ value measured by CPET and superior to DASI and VSAQ (Figure 2D–F). Density plots per indication of CPET are displayed above and on the right side of the axis. The density plots on the y-axis of the FitMáx indicate that most of the results from the subjects are within the 95% LoA.

Discussion

Cardiorespiratory fitness (CRF) is a paramount aspect of health, but currently often overlooked in clinical medicine.^{2–6} We developed the FitMáx containing only three single-answer questions to estimate CRF. The $\text{VO}_{2\text{peak}}$ estimated by the FitMáx showed a strong correlation ($r=0.94$) and an almost perfect agreement ($\text{ICC}=0.93$) with $\text{VO}_{2\text{peak}}$ objectively measured by CPET. The FitMáx showed a $\text{SEE}=4.14 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ in the current study population. The validation was performed in a heterogeneous population of both healthy subjects and patients with variety in age and a wide CRF range. Therefore, FitMáx proves to be applicable in young fit individuals, elderly and patients.

In our study population, FitMáx showed superior results compared with the DASI and VSAQ, which are currently most often used in healthcare to estimate CRF.^{17,18} The FitMáx shows a good performance in a wide range of CRF and only has a ceiling effect in subjects with a very high CRF, in contrast to DASI.^{17,51} A possible explanation of these findings could be that activities included in the VSAQ and DASI are more difficult to recognize for the Dutch population,

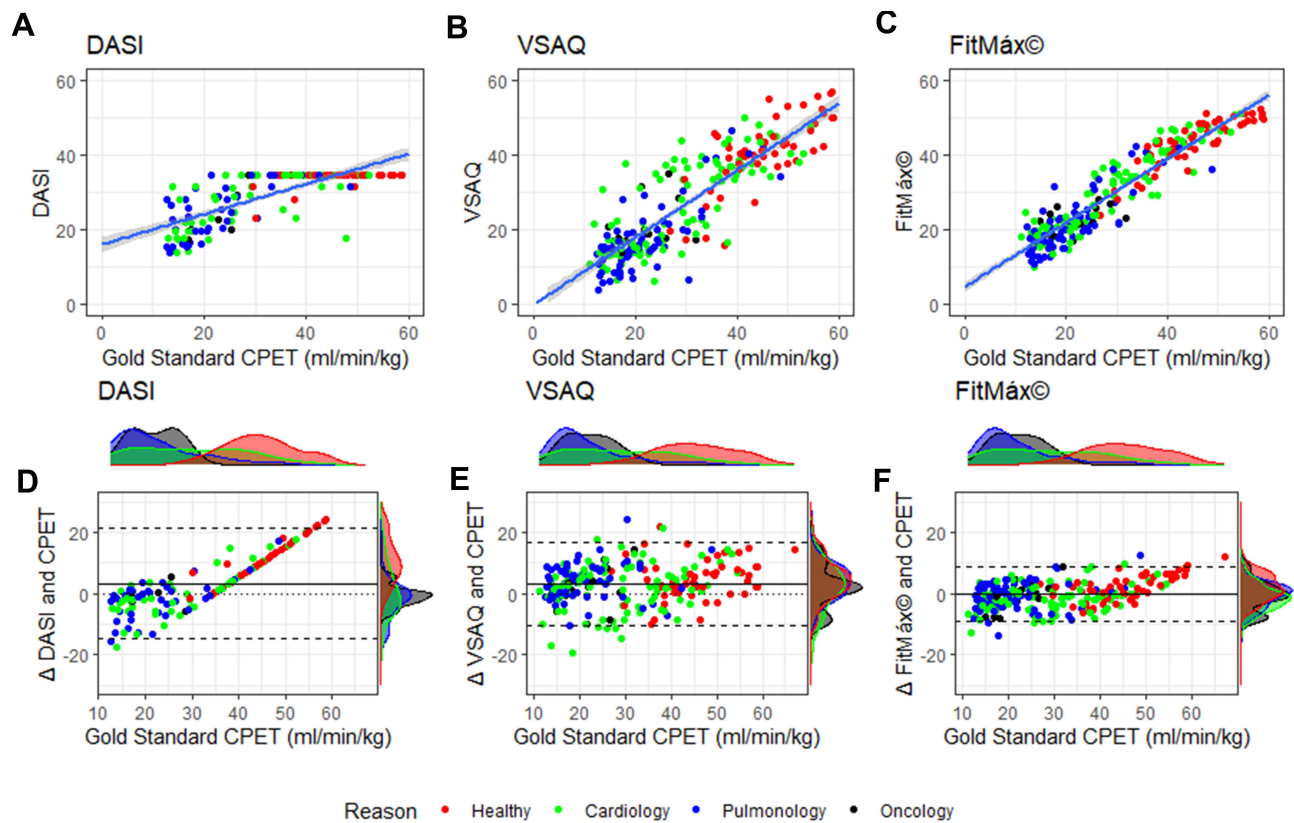

Figure 2 (A–C) Scatterplots with identity line (ie perfect prediction) for FitMáx, DASI and VSAQ; **(D–F)** Bland Altman plots for DASI, VSAQ and FitMáx, above and on the right side of the axis histograms are plotted per reason of the CPET visit. The colors indicate the reason of the CPET visit. The dashed lines represent the limits of agreement, from -1.96 SD to $+1.96$ SD. The solid line represents bias and the dotted line represents the zero bias line.

Abbreviations: CPET, cardiopulmonary exercise testing; DASI, Duke Activity Status Index; min, minutes; mL, milliliters; kg, kilograms; VSAQ, Veterans Specific Activity Questionnaire.

compared to the activities included in the FitMáx.¹⁹ Moreover, the FitMáx© enables subjects to rate their capacity for three activities separately on an increasing scale, instead of using several activities in one question. The ability to complete the FitMáx in the current study was rated on a scale from 1–10 with a median and interquartile range of 7 (8–9).

Other Instruments

More recently, the CLINIMEX aerobic fitness questionnaire (C-AFQ) was developed, as a questionnaire-based prediction model for CRF.⁵² Despite a high correlation with CPET ($r=0.91$), C-AFQ leaves considerable inaccuracy in the estimation of VO_{2max} ($SEE=5.39$ mL·kg⁻¹·min⁻¹). Compared to the original C-AFQ study, correlation, SEE and bias

Table 3 Statistics Validation of the Prediction Model Including Walking, Stair Climbing and Cycling Capacity Separately

with LoA are better for the FitMáx in the current study population.⁵² Moreover, an interview was used to complete the C-AFQ in the validation study, this could have led to a high correlation ($r=0.91$). This phenomenon is also seen in the validation of the DASI.¹⁷

Bradshaw et al developed a questionnaire-based prediction model, and reached a correlation of $r=0.91$ with CPET and $SEE=3.63 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$ in the original research.⁵³ However, the population in the Research of Bradshaw et al was small (100 participants) and had a relatively good CRF (mean $VO_{2\text{max}} 39.96 \text{ mL}\cdot\text{kg}^{-1}\cdot\text{min}^{-1} \pm 9.54$).⁵³ This potentially leads to limited applicability in clinical cases, as CRF is often less high in patients.

Finally, the HUNT study developed a prediction model to estimate $VO_{2\text{peak}}$ that included age, physical activity, waist circumference, and resting heart rate.⁵⁴ This approach is currently advised by the American Heart Association.² However, applicability is limited to settings where such measurements are available. Correlation, SEE and bias reported in the HUNT study were worse than in the current FitMáx study, but results were obtained on study-specific populations only.⁵⁴ Therefore, to draw conclusions on clinometric properties, the mentioned questionnaires should be compared within the same study population.

Strengths of Current Study

The strength of our study lies in direct comparison of the ability of self-reported questionnaires to estimate $VO_{2\text{peak}}$, with $VO_{2\text{peak}}$ objectively measured by CPET, in a diverse population of healthy persons and patients with a wide range of CRF.

Limitations of Current Study

The study population consisted of mainly male subjects (74%). Analyses on sex showed that FitMáx was able to estimate CRF accurately in both men and women. Nevertheless, to enhance the interpretability of the results for female subjects, more data should be collected. No cross-cultural validations of VSAQ and DASI were available in Dutch, so the translation of the questionnaires was done by the researchers. For international use, the question about the maximum cycling capacity may be a limitation in the applicability of the FitMáx. However, estimated $VO_{2\text{peak}}$ based on the FitMáx without the maximum cycling capacity still reached a correlation of $r=0.90$ (0.88–0.92) with measured $VO_{2\text{peak}}$. Despite the high correlation, the LoA are still relatively large indicating that discrepancies between patients' self-reported and measured exercise capacity occur.⁵⁵ Also the FitMáx estimates CRF, but does not diagnose the underlying limitation. FitMáx should not be considered as a full replacement for CPET, but rather a complementary tool to be used in settings where exercise testing is unavailable.

Clinical Relevance of FitMáx

In the current study no physician or healthcare provider was involved in completing the FitMáx. Also DASI and VSAQ were evaluated as strictly self-reported measures for CRF. For the Dutch population, the three questions of FitMáx are easy to relate to, and their sex, age, and BMI are usually known or easy to assess. For healthcare professionals, there is a well-known, single result of the questionnaire: $VO_{2\text{peak}}$. This is clinically applicable as an estimate to stratify the risk of patients with low CRF, who may benefit from more extensive diagnostic exercise testing or to discern the optimal protocol for clinical exercise testing. On the other hand the results of the FitMáx can be used to measure and monitor the effects of an exercise intervention or rehabilitation programme.

Implications for the Future

To enhance clinical applicability of the FitMáx, future studies will focus on the ability to monitor changes in CRF over time and comparison with other clinical exercise tests. This would be especially useful in oncologic patients who participate in rehabilitation programmes or surgical patients in (p)rehabilitation programmes. It may also contribute in the risk assessment before surgery. We also intend to add a question about daily activities to further improve the accuracy and applicability of the FitMáx.

To enable healthcare professionals and researchers in using the FitMáx questionnaire, we have developed an online platform (www.fitmaxquestionnaire.com), where we invite researchers to collaborate with us to further improve and

validate the questionnaire. The online platform provides up-to-date information about the questionnaire and research projects. In addition, a technical interface has been developed to implement the FitMáx into third party applications. More information about our research group, hospital and FitMáx can be found on <https://www.mmc.nl/english/fitmax/>.

Conclusion

Cardiorespiratory fitness is of paramount importance in healthcare, given its substantial relation to survival and quality of life. To tailor treatment and exercise interventions, it is important to measure or estimate CRF. The FitMáx consists of only three questions and is a simple tool to estimate CRF accurately.

Abbreviations

BMI, Body Mass Index; C-AFQ, CLINIMEX Aerobic Fitness Questionnaire; COPD, Chronic Obstructive Pulmonary Disease; CPET, Cardiopulmonary Exercise Testing; CRF, Cardiorespiratory Fitness; DASÍ, Duke Activity Status Index; FRIENDS, Fitness Registry and Importance of Exercise National Database; GOLD, Global initiative for chronic Obstructive Lung Disease; ICC, Intraclass Correlation Coefficient; IQR, Interquartile Range; MET, Metabolic Equivalent of Task; Máxima MC, Máxima Medical Center; r , Pearson correlation coefficient; R^2 , Coefficient of determination; RER, Respiratory Exchange Ratio; SEE, Standard Error of the Estimate; VO_{2max} , maximum oxygen uptake; VO_{2peak} , peak oxygen uptake; VSAQ, Veterans Specific Activity Questionnaire.

Data Sharing Statement

More information on the data gathered, the analysis used, and calculations used in the model is available upon reasonable request. The use of FitMáx is free when used from the website or when incorporated in studies that help us to further validate the questionnaire in different settings and populations. In addition, there is a commercial licensed model available for usage of the questionnaire in different settings. More information can be found on www.fitmaxquestionnaire.com.

Ethics Approval

The authorized Medical Research Ethics Committee of Máxima Medical Center issued a “non WMO acknowledgement” for this study (reference number N18.051). All subjects provided written and/or oral consent for participation in compliance with the declaration of Helsinki.

Acknowledgments

We would like to thank J. Dieleman, L. Bacas, A. den Bresser and J. Schellekens for their contribution to this research. Moreover, we would like to thank J. van der Elsen, S. Bell, J. de Koning, T. Buscop and M. van Nieuwburg for helping with the forward backward translation method to provide the questionnaire in English.

Funding

This work was partially funded by the Stichting SOS and by the National Foundation Against Cancer (NFtK).

Disclosure

Miss Renske Meijer reports grants from Stichting SOS, grants from National Foundation Against Cancer (NFtK), during the conduct of the study. The authors report no other conflicts of interest in this work.

International Journal of General Medicine

Dovepress

Publish your work in this journal

The International Journal of General Medicine is an international, peer-reviewed open-access journal that focuses on general and internal medicine, pathogenesis, epidemiology, diagnosis, monitoring and treatment protocols. The journal is characterized by the rapid reporting of reviews, original research and clinical studies across all disease areas. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/international-journal-of-general-medicine-journal>
