Abstract: The gut microbiota is a remarkable asset for human health. As a key element in the development and prevention of specific diseases, its study has yielded a new field of promising biotherapeutics. This review provides comprehensive and updated knowledge of the human gut microbiota, its implications in health and disease, and the potentials and limitations of its modification by currently available biotherapeutics to treat, prevent and/or restore human health, and future directions. Homeostasis of the gut microbiota maintains various functions which are vital to the maintenance of human health. Disruption of the intestinal ecosystem equilibrium (gut dysbiosis) is associated with a plethora of human diseases, including autoimmune and allergic diseases, colorectal cancer, metabolic diseases, and bacterial infections. Relevant underlying mechanisms by which specific intestinal bacteria populations might trigger the development of disease in susceptible hosts are being explored across the globe. Beneficial modulation of the gut microbiota using biotherapeutics, such as prebiotics, probiotics, and antibiotics, may favor health-promoting populations of bacteria and can be exploited in development of biotherapeutics. Other technologies, such as development of human gut models, bacterial screening, and delivery formulations eg, microencapsulated probiotics, may contribute significantly in the near future. Therefore, the human gut microbiota is a legitimate therapeutic target to treat and/or prevent various diseases. Development of a clear understanding of the technologies needed to exploit the gut microbiota is urgently required.

Keywords: gut microbiota, human health, dysbiosis, biotherapeutics, probiotics, microencapsulation

Introduction

The human gastrointestinal tract houses a huge microbial ecosystem, the gut microbiota. This intestinal ecosystem is partially responsible for maintaining human health. However, particular changes in the ecosystem might contribute to the development of certain diseases. With this in mind, there is a need for an exhaustive review on the functions of the gut microbiota, occurrence of gut dysbiosis (alteration of the microbiota), mechanisms by which intestinal bacteria can trigger development of disease, how this ecosystem can be exploited for understanding human health, development of biotherapeutics, expert opinion on current biotherapeutics, and future perspectives. This review presents a descriptive and comprehensive analysis on “the good, the bad, and the ugly” of the gut microbiota, and methods to study these and their modulation of human health.

Composition

The human gut microbiota represents the trillions of microorganisms located in our intestines. Collectively, the number of intestinal microbial cells is 10 times greater than the number of human body cells.¹ It was recently demonstrated that the microbiome, which represents the collective genomes of the gut microbiota, is approximately 150 times larger than the human gene complement, with an estimated set of 3.3 million microbial genes.² Seven bacterial divisions constitute the gut microbiota, ie, *Firmicutes*, *Bacteroides*, *Proteobacteria*, *Fusobacteria*, *Verrucomicrobia*, *Cyanobacteria*, and *Actinobacteria*, with *Firmicutes* and *Bacteroides* being the most abundant species.³ Bacterial communities exhibit quantitative and qualitative variations along the length of the gastrointestinal tract due to host factors (eg, pH, transit time, bile acids, digestive enzymes, and mucus), nonhost factors (eg, nutrients, medication, and environmental factors), and bacterial factors (eg, adhesion capacity, enzymes, and metabolic capacity).⁴

Acquisition

It is generally accepted that humans are born with a sterile gut. However, new evidence suggests that colonization of the gastrointestinal tract starts before birth, with the fetus ingesting amniotic fluid containing microbes.⁵ Subsequently, intestinal colonization is acquired during the first months of life, with aerobic and facultative anaerobic colonization, followed by obligate anaerobes and *Bifidobacteria*.⁶ Establishment of the gut microbiota is recognized as a complex process influenced by factors at the level of the host and of the microbes themselves.³

Exploration

Study of the composition of human colonic microbiota and metabolism has methodological and ethical limitations. Attempts to circumvent these limitations have led to the development of models. In vitro models are of interest for ecological, fermentation, and metabolic studies.⁷ These provide reproducible results and controlled mechanistic studies (Table 1). Fecal inocula are most often utilized as a representation of the intestinal microbiota.² In vivo models for the exploration of the gut microbiota encompass various species of laboratory animals. Effects of the indigenous microbiota on the host have been determined by gnotobiology, ie, selective colonization of germ-free animals with defined organisms.⁸

Analysis

Until recently, the analysis of bacterial ecosystems was performed by growth on defined media, which has some limitations because this method is labor-intensive and, more importantly, only 80% of stool bacteria can be cultivated.^{6,8} As a consequence, new molecular techniques have been developed. In terms of qualitative measurements of the microbiota, techniques such as fingerprinting (denaturing gradient gel electrophoresis), terminal restriction fragment length polymorphism, ribosomal intergenic spacer analysis, and 16S ribosomal RNA sequencing are widely used.⁸⁻¹¹ Specifically, genome sequencing has provided tremendous information in the microbial world, spearheading technologies such as microarrays.⁸ New automated parallel sequencing technologies, based on the 16S ribosomal RNA gene present in all prokaryotes, can offer a cost-effective solution for rapid sequencing and identification of bacterial species of the gut. Prominent high-throughput sequencing technologies include 454 Life Sciences' Genome Sequencer™, Applied Biosystems' SOLiD™ 3 Plus system, Illumina's Genome Analyzer Iix, and other technologies developed by Affymetrix, Helicos, Qiagen, and Microchip. For quantitative measurements of the gut microbiota, fluorescence in situ hybridization, catalyzed reporter deposition-fluorescence in situ hybridization, quantitative polymerase chain reaction, and scanning electron microscopy in situ hybridization, can be useful.^{8,10-12} Fluorescence in situ hybridization allows for the visualization of microorganisms in their natural environment using labeled probes specific for selected bacteria. This method has been used for the determination of changes in the bacterial populations of fecal homogenates and in tissue sections from individuals with certain diseases. Catalyzed reporter deposition-fluorescence in situ hybridization is a modified method of fluorescence in situ hybridization which allows for in situ amplification using horseradish peroxidase, enhancing bacterial cell detection in samples where ribosomal RNA is insufficient for fluorescence in situ hybridization.¹² Real-time quantitative polymerase chain reaction is a recent and widely used technique for exploration of the roles of gut microflora in health and disease, based on the presence of specific RNA sequences. There is also scanning electron microscopic in situ hybridization which uses deposition of nanogold particles to enable detection¹² (Table 2). Finally, metagenomics is an approach to analyze the genomic content of microbial communities living in a particular niche, such as the gut, and for identifying and quantifying the bacterial species present.⁸

Table 1 In vitro and in vivo models of the human gut microbiota and their potentials and limitations

Models	Description	Main use	Limitations	References
In vitro				
Static batch system	Fresh feces or colonic contents suspended in buffer solution	Short-term metabolic and enzymatic studies	Rapid change in ecosystem composition	7
Semicontinuous batch system	Chemostat culture system of semicontinuous flow Inoculated with defined bacteria, feces, or colonic content	Long-term studies on metabolic, ecologic, and dietary fermentation	Host factors are ignored Stability of ecosystem is assumed	7
Continuous batch system	Chemostat culture system of continuous flow Inoculated with defined bacteria, feces, or colonic content	Long-term studies on metabolic, ecologic, and dietary features of GI microbiota	Host factors are ignored Complex system to set up Stability of ecosystem is assumed	7,105,106
In vivo				
Laboratory animals	Fresh feces or colonic contents from conventional microbiota animals	Metabolic, ecological, and preclinical studies	Differences between animals and humans gut microbiota composition	7,109,112
Gnobioc animals	Germ-free laboratory animals colonized with defined organisms or transferred microbiota from a laboratory animal or a human volunteer	Host-bacterial and bacterial-bacterial interaction studies	Alteration of bacterial interactions	7,10,49
Human volunteers	Fresh feces or colonic contents from human volunteers	Metabolic, ecological, chemical, and clinical studies	Ethical issues Relevance of feces/colonic contents to represent the overall GI microbiota	7,36,42

Abbreviation: GI, gastrointestinal.

The good

The gut microbiota performs essential functions in maintenance of health, including having protective, structural, and metabolic roles.

Essential metabolic functions

Metabolic functions of the gut microbiota include production of vitamin, amino acid synthesis, and bile acid biotransformation. Bile acid biotransformations, performed by microbial enzymes, have implications for cholesterol and glucose metabolism.¹³ Importantly, the microbiome provides biochemical pathways required for the fermentation of nondigestible substrates and endogenous mucus. Through fermentation, bacterial growth is stimulated, producing short-chain fatty acids and gases.¹⁴ The major short-chain fatty acids produced are acetate, butyrate, and propionate. Other bacterial end products include lactate, ethanol, succinate, formate, valerate, caproate, isobutyrate, 2-methyl-butyrates, and isovalerate. Bacterial fermentation is present in the cecum and colon, where the short-chain fatty acids are absorbed, stimulating the absorption of salts and water. One property of short-chain fatty acids is their trophic effect on the intestinal epithelium.¹⁴ Butyrate is the preferred energy source for epithelial cells, and is almost entirely cleared by the colonic epithelium. Acetate is the principal short-chain fatty acid in

the colon and the primary substrate for cholesterol synthesis. Finally, propionate supplementation in the diet was shown to reduce cholesterol levels in vivo.^{15,16} Clinical trials have yet to confirm these observations. Therefore, the metabolic activities performed by the gut microbiota are various and essential for host metabolism (Figure 1).

Ensures protection

Pathogen displacement or “colonization resistance” is an accepted function of the gut microbiota. Commensal organisms prevent pathogenic colonization by competing for attachment sites and nutrients, and also through the production and secretion of antimicrobials. Those mechanisms are relevant for reducing the level of lipopolysaccharides, peptidoglycans, bacterial CpG-DNA motifs, and superantigens, which can all be detrimental to the host.¹⁷ The indigenous microbiota is also essential for development of the immune system.¹⁸ Germ-free mice display underdeveloped lymphatic systems, with fewer Peyer’s patches and isolated lymphoid follicles.^{19,20} Moreover, intestinal dendritic cells are fewer in germ-free animals, and there is evidence to support a role for bacterial signals in B cell development.^{21,22} Furthermore, signals from intestinal bacteria appear important for the development of regulatory T, T helper type 1 and 2 cells, and T helper 17 cells.^{23–25} The first commensal

Table 2 Available techniques for human gut microbiota characterization

Techniques	Description	Main use	Limitations	Reference
Culture-based	Defined media used to isolate bacterial populations	Quantification/characterization of isolated colonies	Bacteria uncultivable Species/strains level hardly detected Labor-intensive	8,6
16S rRNA sequencing	Species/strains level sequencing	Bacterial identification	Extensive data analysis	8,9–11
DGGE	Denaturation of small PCR amplicons from extracted community DNA and gel migration	Comparative studies	PCR amplicons too small to sequence information	8,11
Terminal RFLP	Denaturation of full-length 16S rRNA PCR amplicons from extracted community DNA and gel migration	Communities comparison	Limited taxonomic resolution	8,11
RIS analysis	PCR amplification of IS region between 16S-23S rRNA genes hybridized to fluorescently labeled primers	Characterization of complex bacterial communities	Complex bacterial identification Lack of extensive database	8,11
FISH	Hybridization of fluorescently labeled oligonucleotide probes to 16S rRNA specific of targeted bacteria	Quantification of targeted bacterial groups/species	Novel species/strains unidentified	8,10,11
CARD-FISH	Modified FISH method: in situ amplification using horseradish peroxidase	Bacteria quantification if FISH inadequate	Novel species/strains unidentified	12
SEM in situ hybridization	Combination of in situ hybridization and SEM	Quantification of targeted bacterial groups/species	Novel species/strains unidentified	12
Quantitative PCR	Specific bacterial groups/species targeted from a mix culture by quantitative PCR primers	Quantitative studies of complex system	Novel species/strains unidentified Strain required for standard curve	8,10,11
DNA microarray	Set of regular arranged spots of DNA recognition elements positioned on microscopic slides	Screening of human gut microbial communities	Low detection limit Hybridization biases Novel species/strains unidentified	8

microorganism molecule shown to influence an immune response beneficially was capsular polysaccharide A, produced by *Bacteroides fragilis*.²⁶ Short-chain fatty acids, such as butyrate, may also exert potent immunomodulatory effects by suppressing nuclear factor- κ B activation and/or by acting on G-coupled receptors, as demonstrated with acetate.^{27,28} These concepts illustrate a dynamic relationship between the immune system and the microbiota. The intestinal mucosa averts threats by signaling to the innate immune system through pattern recognition receptors, such as toll-like receptors. Pattern recognition receptors recognize and bind to specific microbial macromolecules, referred to as microbial-associated molecular patterns. These include lipopolysaccharide, flagellin, peptidoglycan, and N-formylated peptides. In the intestinal mucosa, activation of pattern recognition receptors initiates nuclear factor- κ B pathways, mitogen-activated protein kinase, and caspase-dependent signaling cascades. These lead to the production

and release of protective peptides, cytokines, chemokines, and phagocytes. The result can be a protective response to commensal bacteria, an inflammatory response to pathogenic organisms, or a trigger of apoptosis. Therefore, commensal bacteria of the gastrointestinal tract play active roles in the development and homeostasis of the immune system, as shown in Figure 1.

Structural and histological function

The microbiota ensures intestinal structure and function. Firstly, the mucus layer, which reflects the balance between mucus secretion and bacterial degradation, constitutes an obstacle to the uptake of antigens and proinflammatory molecules.²⁹ There is evidence indicating that butyrate reinforces the colonic defense barrier by inducing the secretion of mucins, trefoil factors, and antimicrobial peptides.³⁰ Secondly, some bacterial communities may strengthen the barrier at the level of the tight junctions,

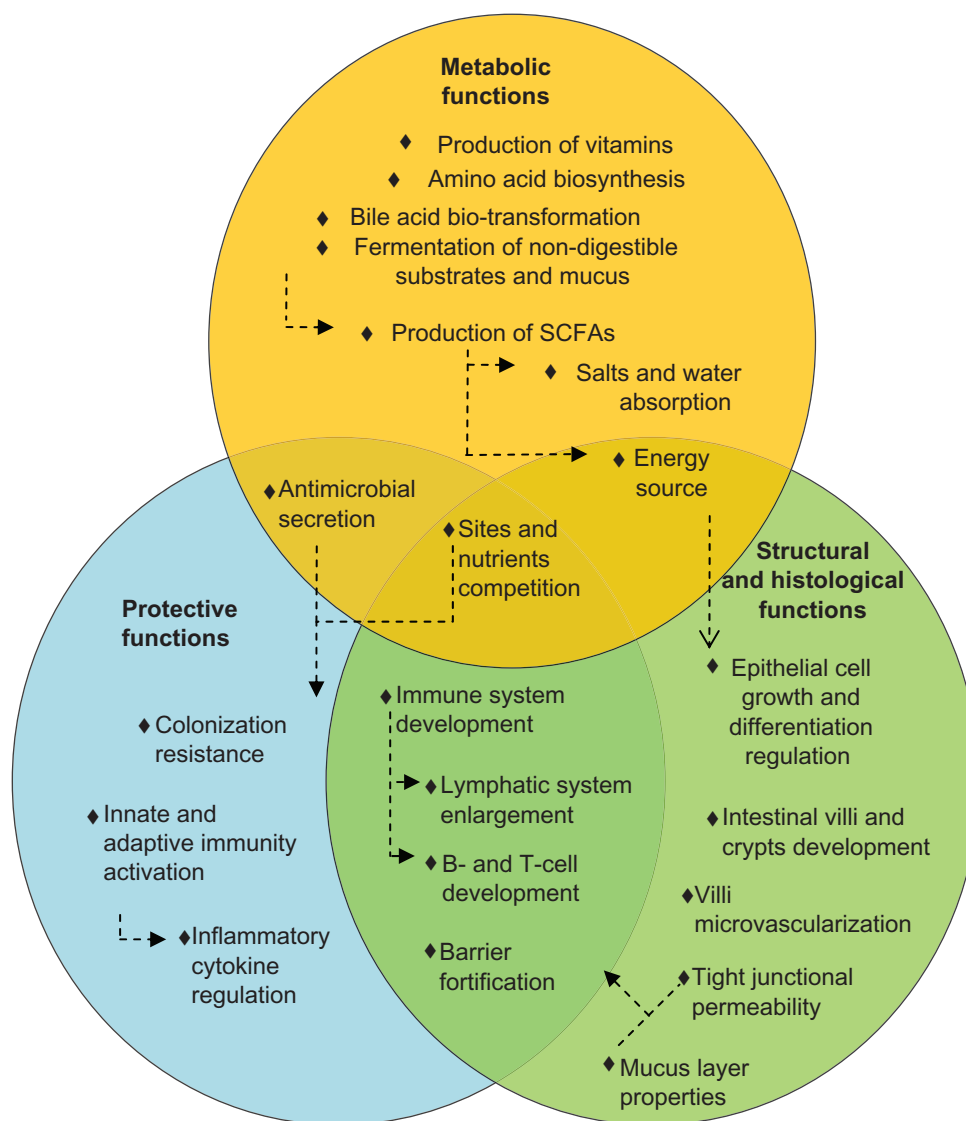

Figure 1 Main beneficial functions of the human gut microbiota. Circles represent the three principal classes of functions performed by the bacteria that inhabit the gut. Arrows represent causal relationships.

Abbreviation: SCFA, short chain fatty acid.

ie, protein clusters that form a barrier between the lumen and the lamina propria. Moreover, the gut microbiota is involved in cell and tissue development. Butyrate regulates cell growth and differentiation, inhibiting transformed cell growth while encouraging reversion of cells from a neoplastic to a non-neoplastic phenotype.³¹ The cecum villi are longer and wider, while the colonic crypts are shorter and contain fewer cells in germ-free than conventionally reared animals, possibly due to an altered rate of epithelial cell turnover or to anatomical changes arising from a reduction in bacterial count.³² Moreover, indigenous microbes shape the development of the villus microvasculature, as demonstrated in germ-free animals colonized during or after completion of postnatal gut development.³³ Therefore,

most of the structural and morphological development of the gut contributes to and manages the gut bacterial system (Figure 1).

The bad

Dysbiosis is a state in which the microbiota becomes altered as a consequence of an alteration in the composition of the microbiota, a change in bacterial metabolic activity, and/or a shift in local distribution of communities. Many factors can alter the gastrointestinal ecosystem, including antibiotics, psychological and physical stresses, radiation, altered peristalsis, and dietary changes.³⁴ At present, the focus is on the description of dysbiosis in a plethora of human disorders.

Autoimmune disease

Autoimmune diseases occur when the body's immune system attacks and destroys healthy cells and tissues, as is the case in type 1 diabetes mellitus, celiac disease, inflammatory bowel diseases, and allergic asthma. Most often, the immune response is initiated by unknown factors. Alteration of the gut microbiota as a result of modern lifestyles is an attractive hypothesis to explain the rise in prevalence of celiac disease, type 1 diabetes mellitus, and inflammatory bowel diseases.

Celiac disease is an inflammatory disease of the small intestine that is triggered and maintained by the storage proteins of wheat, barley, and rye. Studies have investigated the composition of the microbiota in patients with celiac disease. Fecal samples from patients with celiac disease had reduced the proportions of *Bifidobacterium*, *Clostridium histolyticum*, *Clostridium lituseburense*, *Faecalibacterium prausnitzii*, and increased proportions of *Bacteroides/Prevotella*.³⁵ In addition, increased proportions of total and Gram-negative bacteria, with an increase in *Bacteroides* and *Escherichia coli* in biopsies of patients with celiac disease in the active as compared with inactive disease state and control individuals, was shown by fluorescence in situ hybridization coupled with flow cytometry.³⁶

Type 1 diabetes mellitus, characterized by insulin deficiency resulting from immune-mediated destruction of pancreatic β cells, is thought to be triggered by environmental factors in genetically susceptible individuals. Given that antibiotics prevented type 1 diabetes mellitus in biobreeding diabetes-prone rats and in nonobese diabetic mice, alteration of the microbiota has been associated with progression of type 1 diabetes mellitus.^{37,38} Moreover, evidence shows that bacterial communities from biobreeding diabetes-prone and diabetes-resistant rats differ, marked by a higher abundance of *Lactobacillus* and *Bifidobacterium* in diabetes-resistant rats.³⁹

Inflammatory bowel diseases include ulcerative colitis and Crohn's disease. Crohn's disease is characterized by patchy and transmural inflammation that may affect any part of the gastrointestinal tract, while ulcerative colitis is a chronic episodic inflammatory condition that involves only the large bowel.⁴⁰ There is evidence that species belonging to the normal gut microbiota are involved in the etiology and/or maintenance of inflammatory processes. Reduced microbial diversity, increased *Bacteroidetes* and *Enterobacteriaceae*, and decreased *Firmicutes* were all observed in patients with inflammatory bowel diseases.⁴¹ Another clinical study observed that *Eubacterium rectale*, *B. fragilis*, *Bacteroides vulgatus*, *Ruminococcus albus*, *R. callidus*, *R. bromii*, and

F. prausnitzii were 5–10-fold more abundant in healthy subjects than in patients with Crohn's disease, while *Enterococcus* spp, *C. difficile*, *E. coli*, *Shigella flexneri*, and *Listeria* spp were more abundant in the Crohn's disease group.⁴² Thus, inflammatory bowel diseases, celiac disease, and type 1 diabetes mellitus are autoimmune diseases marked by an alteration of the gut microbiota. Autoimmune regulation may be linked with the disruption of the intestinal ecosystem.

Allergic disease

The etiology of allergic diseases is ambiguous. They may be initiated and maintained by environmental factors associated with a change in gut microbiota. Correlations between allergic disease and altered fecal microbiota, antibiotic use, and dietary changes have been made.^{43–45} Studies of the microbiota in allergic patients have shown decreased intestinal *Bifidobacteria* counts, an increased prevalence of *B. fragilis*, and higher counts of *Staphylococcus aureus* and *E. coli*.^{46–48} A study reported higher levels of *Bifidobacterium adolescentis* and *Lactobacilli* Group I (*Lactobacillus rhamnosus*, *L. paracasei*, *L. casei*) in fecal samples of nonallergic compared with allergic children.⁴³ Hence, it is clear that differing gut microbial communities have been observed in allergic patients. Further clinical studies are required on several age-matched groups of allergic versus control individuals classified with short age intervals.

Irritable bowel syndrome

Irritable bowel syndrome is characterized by abdominal pain, bloating, and changes in bowel habit, in the absence of any overt mucosal abnormality. Observations have directed attention towards the gut microbiota, identifying a postinfectious variant of the syndrome, ie, evidence that antibiotics induced a reduction in the microbiota which may be a risk factor, and the proposal that some patients may have bacterial overgrowth in the small bowel.⁴⁹ Studies have demonstrated that patients with irritable bowel syndrome have fewer intestinal *Bifidobacteria*, *Collinsella aerofaciens*, *Coprococcus eutactus*, and *Clostridium cocleatum*, and an increase in *Veillonella* and *Enterobacteriaceae*.^{50–52} Thus, irritable bowel syndrome is associated with abnormal intestinal communities, but their significance in the pathogenesis of irritable bowel syndrome remains unclear.

Metabolic disease

There are genetic and environmental factors that influence obesity, with the impact of the gut microbiota being

well documented. Research on the microbiota of obese mice establishes the link between obesity, weight gain, and intestinal dysbiosis. Findings indicate that a high-fat diet modulates the microbiota independently of obesity.⁵³ Mice genetically predisposed to develop obesity (ob/ob) harbor more *Firmicutes* and fewer *Bacteroidetes*.⁵⁴ Studies in human twins concordant for obesity have demonstrated that the fractional representation of *Bacteroidetes* is directly correlated with leanness.⁵⁵ Moreover, microbiota transplantation from normal chow-fed ob/ob and Western diet-fed wild-type to germ-free wild-type mice caused an adiposity increase greater than that caused by transplantation from wild-type donors fed standard chow.^{56,57} This demonstrates a causal effect of intestinal bacteria on development of obesity. Aberrant development of the microbiota might precede obesity, because the childhood representation of *Bifidobacteria* and *S. aureus* has been suggested to predict the development of adulthood obesity in an inverse and direct manner.⁵⁸ In light of these findings, a study was initiated which demonstrated that total short-chain fatty acids were higher in an obese group and individual short-chain fatty acid proportions shifted towards propionate in overweight subjects.⁵⁹ It is assumed that gut dysbiosis may contribute to the development of obesity.

Type 2 diabetes is characterized by defects in insulin secretion and action. Research has characterized the fecal microbiota composition of adults with type 2 diabetes and showed reduced proportions of *Firmicutes* and *Clostridia*.⁶⁰ The ratios of *Bacteroidetes* to *Firmicutes*, as well as *Bacteroides/Prevotella* to *Clostridium coccoides* and *E. rectale* groups correlated positively with plasma glucose concentration. Similarly, class β -*Proteobacteria* was highly enriched in diabetic individuals and positively correlated with plasma glucose. Other authors have demonstrated that *Prevotella* was associated with healthy groups, while *Bacteroides* and *Parabacteroides* were prevalent in diabetic patients, who also had fewer counts of fecal *B. vulgatus* and *Bifidobacteria*.⁶¹ The evidence demonstrates that metabolic diseases are associated with a shift in the balance of the microbiota. Confirmation of gut dysbiosis in type 2 diabetes patients requires additional clinical trials.

Alcoholic liver disease

Alcoholic liver disease, arising from excessive ingestion of alcohol, is the primary cause of liver failure in the Western world. It has been demonstrated in one study that daily alcohol consumption affects composition of the colonic microbiota.⁶² The authors pointed to a specific fingerprint

of dysbiotic microbiota which could potentially identify susceptible heavy drinkers at high risk for alcoholic liver disease. Further examination is required to support fully the link between gut dysbiosis and alcoholic liver disease.

Bacterial infection

It is well established that a disruption in the commensal microbiota increases susceptibility to enteric infections. Antibiotic-treated mice are particularly useful for studying colitis induced by *Salmonella* spp, *Shigella* spp, and *E. coli* infections. In addition, in murine *Citrobacter rodentium* infections, pathogen colonization is associated with a reduced total density and a relative increase in γ -*Proteobacteria*.⁶³ Furthermore, elderly patients with *C. difficile*-associated diarrhea demonstrate reduced numbers of *Bacteroides*, *Prevotella*, and *Bifidobacteria*, and a greater diversity of facultative species, ie, *Lactobacilli* and *Clostridia*.⁶⁴ The evidence suggests an association between disruption of the gut microbiota and bacterial infections, further accentuating the dysbiosis.

Colorectal cancer

Colorectal cancer is a disease of the Western world, with the most common type being adenocarcinomas which develop from glandular cells lining the wall of the bowel.⁶⁵ Genetic and induced models of intestinal neoplasia have shown that, under germ-free conditions, colitis and tumor formation are reduced compared with monoassociated and conventional animals.⁶⁶⁻⁶⁸ In addition, in vivo colonization of enterotoxigenic *B. fragilis* a human colonic commensal bacteria, has been linked to the development of colorectal cancer.⁶⁹ Furthermore, colorectal cancer patients demonstrate decreased levels of *E. rectale* and *F. prausnitzii* compared with healthy volunteers, and increased populations of *E. faecalis*.⁷⁰ Recently, a clinical trial showed that patients with colorectal cancer had significant elevation of the *Bacteroides-Prevotella* population.⁷¹ Therefore, studies that have examined the gut microbiota in colorectal cancer have reported an association between microbiota and pathogenesis of colorectal cancer. The abnormal profile of bacterial communities, activities, and metabolites in human disease is summarized in Table 3.

The ugly

Altered composition of the human gastrointestinal ecosystem can lead to physiological changes in the intestinal environment, disrupting the functions of the microbiota and having serious consequences for human health.

Table 3 Imbalances of human gastrointestinal bacterial communities in human disease

Increase in	Human disease	Decrease in
Gram negative, <i>Bacteroides-Prevotella</i> , <i>Escherichia coli</i>	Celiac disease	Gram-positive <i>Bifidobacteria</i> , <i>Clostridium histolyticum</i> and <i>C. liteseburensense</i> , <i>Faecalibacterium prausnitzii</i>

Note: Each bacteria group has been shown to be related to the disease, independently of one another.

Altered gut microbiota may trigger serious immune deregulation

The hygiene hypothesis predicts that increased hygiene, use of antibiotics, and sterile food preparation result in isolation of the immune system from positive microbial exposure, favoring susceptibility to immune-mediated disorders.⁷² Epidemiological studies have linked a decreasing burden of infection with a rising incidence of immunological disorders.^{73,74} The presence of environmental viral agents are also associated with the incidence of spontaneous type 1 diabetes.⁷⁵ Furthermore, the microbiota of nonobese diabetic mice deficient for the myeloid differentiation primary response gene 88 (MyD88) signaling molecule protects mice against developing diabetes.⁷⁶ Inactivation of MyD88 leads to gut dysbiosis, further inhibiting the autoimmunity occurring in MyD88^{-/-} germ-free nonobese diabetic mice. These findings support a causal inverse relationship between microbial exposure and immunological disorders.

There are several underlying mechanisms of the hygiene hypothesis, ie: lack of microbial burden in childhood, predisposing the host to allergic disorders due to a T helper type 1/type 2 deviation; defective maturation of regulatory T cells as a consequence of modern lifestyles; antigenic competition from infectious agents inhibiting responses to weak antigens; protection from allergic diseases through mechanisms independent of their constitutive antigens, leading to stimulation of nonantigen-specific receptors; and development of an aggressive immune response caused by genetic hyperimmunity triggered by dysbiosis.⁷² Therefore, the disruption of cross-talk between the commensal microbiota and the

immune system, as a result of modern lifestyles, may lead to development of allergic, autoimmune, and autoimmune-associated diseases (Figure 2A).

Specific gut dysbiosis can engender metabolic endotoxemia

Obesity and type 2 diabetes are associated with chronic low-grade inflammation and endotoxemia. Lipopolysaccharide administration and a high-fat diet lead to an increase in adipose tissue, impaired glucose tolerance, and insulin resistance, while dietary modulation reverses this phenotype.^{77,78} Chronic

Figure 2 Proposed mechanisms whereby an altered microbial balance in the gut can lead to **A**) an increase in immune mediated disorders and **B**) chronic low-grade inflammation.

Abbreviations: Th, T helper type; CD14, cluster of differentiation 14; LPS, lipopolysaccharide; TLR4, toll-like receptor 4.

inflammation, elicited by endotoxemia, may cause activation of the immune system. The importance of gut-derived endotoxins in alcoholic liver disease has also been supported.⁷⁹ Circulating endotoxin levels were increased in mice and rats following chronic alcohol ingestion, while antibiotic treatment provided protection from alcoholic liver disease. In addition, plasma endotoxins were augmented in patients with alcoholic liver disease. The evidence also suggests that endotoxins contribute to the pathogenesis of nonalcoholic fatty liver disease, considered to be a hepatic manifestation of metabolic syndrome and obesity. Indeed, plasma endotoxins are higher in patients with nonalcoholic fatty liver disease and are associated with intestinal overgrowth and induction of hepatic toll-like receptor 4.^{80,81} Gut permeability, which influences the systemic distribution of endotoxins, may further induce metabolic endotoxemia. Mice fed a high-fat diet demonstrate increased gut permeability and metabolic endotoxemia, associated with disruption of tight junction proteins.⁸² Furthermore, an increase in *Bifidobacteria* induced by nutritional supplements is correlated with an improved gut barrier, lower portal lipopolysaccharide levels, and lower inflammatory tone in ob/ob mice.⁸³ Taken together, we suggest that gut dysbiosis, characterized by decreased *Bifidobacteria* and increased lipopolysaccharide release, disrupts the epithelial barrier, resulting in a leaky gut and leading to colonic and systemic inflammation which contributes to alcoholic liver disease, nonalcoholic fatty liver disease, obesity, and type 2 diabetes (Figure 2B). It remains unclear which Gram-negative bacteria are responsible for the increase in lipopolysaccharide.

Bacterial infection might be promoted by gut dysbiosis

Pathogenic bacteria can invade the gastrointestinal tract and infect the body, producing sepsis, shock, multisystem organ failure, and death of the host. The mechanisms by which pathogens overcome obstacles to achieve successful infection are uncertain. Pathogenic infections might be facilitated by disruption of the intestinal ecosystem by environmental factors. A mechanism based on the triggering of the host's immune defenses was elucidated using models of *C. rodentium* (mimicking diarrheal pathogen-associated inflammation), *Campylobacter jejuni* infection, and chemically and genetically induced models of intestinal inflammation are used for altered microbiota investigations.⁶³ An overgrowth of *Enterobacteriaceae* was observed in all models, indicating that inflammation-induced microbiota changes support colonization by aerotolerant bacteria. The inflammatory response, triggered by

the invading pathogen, may function to enhance its colonization, further facilitating its virulence. Thus, alteration of the gut microbiota, initiated by host and environmental factors, may participate in the initiation of diseases caused by infectious agent (Figure 3A).

Abnormal bacterial metabolite levels may trigger cancer

Many etiological bacterial mechanisms have been hypothesized to promote carcinogenesis. Amongst those, hydrogen sulfide, a product of bacterial sulfate reduction, appears to be linked to the incidence of chronic disorders, such as ulcerative colitis and colorectal cancer. Because DNA strand breaks are associated with mutation and promotion of carcinogenesis, bacterial hydrogen sulfide may be responsible for the induction of mutations in the development of sporadic colorectal cancer.⁸⁴ Reactive oxygen intermediates also cause DNA damage, and their numbers are higher in chronic inflammation and colorectal cancer, as observed in the fecal matrix.⁸⁵ In addition, hydrophobic bile acids have been shown to promote colorectal carcinogenesis by inducing micronuclei formation, mitotic perturbations, and decreases in spindle checkpoint proteins.⁸⁶ Intestinal bacteria may also function as promoters of carcinogenesis by increasing the progression of chemically induced aberrant crypt foci.^{87,88} Therefore, despite limited studies on the occurrence of gut dysbiosis and tumorigenesis, we bring to a close the mechanisms that support the implication of detrimental intestinal bacteria in promoting carcinogenesis (Figure 3B).

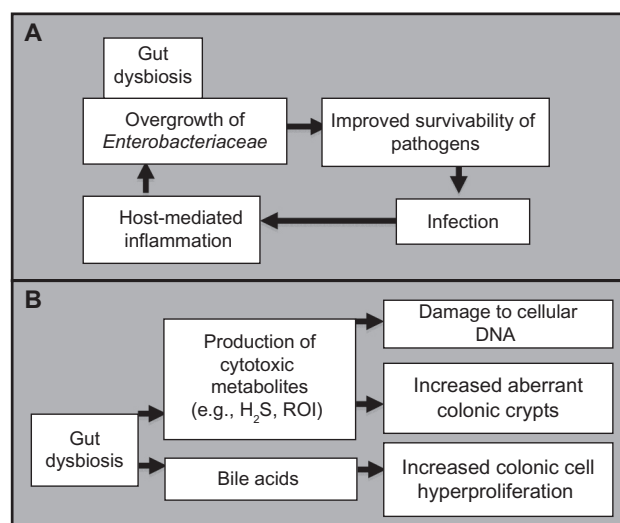

Figure 3 Proposed mechanism whereby an altered microbial balance in the gut can **A)** be driven by foreign pathogenic invasion and further increase the likelihood of future infections, and **B)** lead to the promotion of carcinogenesis. **Abbreviations:** H₂S, hydrogen sulfide; ROI, reactive oxygen intermediate.

Gut microbiota alters energy and lipid metabolism

Gordon et al investigated the influence of microbiota on fat and lipid metabolism, demonstrating that reared mice have more body and gonadal fat than germ-free mice, despite reduced chow consumption. The increase in fat was accompanied with increased fasting glucose and insulin levels and an insulin-resistant state.⁸⁹ Transplantation of the microbiota from ob/ob mice to germ-free mice resulted in a greater increase in body fat than from lean donors.⁵⁶ Two mechanisms are suggested. First, colonization of the gut may suppress expression of fasting-induced adipose factor, increasing the activity of lipoprotein lipase, leading to an increased uptake of fatty acids and triglyceride storage. The second mechanism is based on the processing of dietary polysaccharides by bacteria that may increase hepatic lipogenesis through expression of sterol response element binding protein 1 and carbohydrate response element binding protein. Other authors suggest that the complex formed by short-chain fatty acids and G protein-coupled receptor 41 may increase circulating levels of peptide YY, which may further increase energy extraction from the diet.⁹⁰ It was also demonstrated that in the absence of gut microbiota, AMP-activated protein kinase activity is constitutively higher in muscle, leading to higher phosphorylation of its specific target, acetyl CoA carboxylase, promoting mitochondrial fatty acid oxidation.⁹¹ Finally, the microbiota may affect insulin resistance and steatosis by regulating choline metabolism.⁹² Thus, alteration of the gut microbiota causes defective energy and lipid metabolism leading to the development of metabolic disease (Figure 4).

Alter the gut microbiota to favor human health

The relationship between health and the gastrointestinal system is established. Due to the inherent plasticity of microbiota, one can consider exploiting it to develop biotherapeutics.

Probiotics

Probiotics are “live microorganisms, which, when administered in adequate amounts, confer a health benefit on the host”.⁹³ Probiotics have been shown to have effects on irritable bowel diseases, metabolic syndromes, enterocolitis, immunomodulation, pathogen defense, and urogenital infections.^{94–96} Mechanisms of probiotics include remodeling of microbial communities and suppression of pathogens, suppression of proinflammatory factors, effects on epithelial

cell differentiation, and proliferation and promotion of the intestinal barrier.⁹⁷

Microencapsulation and other methods for targeted delivery

Microencapsulation, which provides living cells with a physical protection barrier, is primarily used to improve probiotic activity during gastrointestinal transit, while allowing the diffusion of metabolites and substrates into and out of the capsule. Secondly, it offers a bacterial delivery system targeted to a specific part of the gastrointestinal tract. Thirdly, microencapsulation ensures immunomodulation by preventing interaction between the host immune system and entrapped probiotic bacterial cells.^{98,99} In addition, there are other excellent formulations available for delivery of probiotic cells to achieve optimal clinical benefits.

Prebiotics

Prebiotics are “nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or the activity of one or a limited number of bacteria in the colon, and thus improves host health”.¹⁰⁰ A prebiotic should not be hydrolyzed by human intestinal enzymes, but selectively fermented by bacteria, benefiting the host. Effects of prebiotic administration include reduced triglyceride levels, improved postprandial glucose levels, and reduced intestinal permeability and inflammation.^{100–102} In addition to prebiotics, known foods and drugs are also being developed to enhance the growth of health-promoting bacterial cell populations in the gastrointestinal tract, with the aim of preventing or treating a number of diseases.

Symbiotic association of probiotics and prebiotics

It has been hypothesized that in combining probiotics and prebiotics, one would not only achieve the combined effects of the two components, but also a synergistic effect. This is the principle on which symbiotics are based.¹⁰³

Antibiotics combined with probiotics

The evidence suggests that probiotic bacteria suppress gastrointestinal pathogens and potentiate antibiotic efficacy by production of antibacterial factors, including bacteriocins.⁹⁷ With the use of antibiotic drugs, bacterial overgrowth can be controlled, and translocation in specific conditions of increased risk can be prevented.⁸³ In brief, strong evidence is available that probiotics, prebiotics, and antibiotics can successfully exploit the natural microbial composition of

Figure 4 Proposed mechanisms by which an altered balance of the gut microbiota can lead to dysfunctional energy and lipid metabolism.

Abbreviations: AMPK, AMP-activated protein kinase; ChREBP, carbohydrate regulatory element binding protein; FIAF, fasting-induced adipose factor; GPR41, G protein-coupled receptor 41; LPL, lipoprotein lipase; PYY, protein YY; SCFA, short-chain fatty acid; SREBP1, sterol regulatory element binding protein 1.

the gut to treat and/or prevent diseases for improving human health and well being.

Future directions

Advances in exploring and modeling the microbiota are generating a wealth of knowledge about human health and disease, and contributing to the development of new biotherapeutics. Significant advances have been made in the selection and characterization of specific probiotic cultures and/or prebiotics and subsequent substantiation of health claims relating to their consumption. However, there is still much skepticism in the medical community with respect to the effects demonstrated. Firstly, the disease model used affects the results significantly. Secondly, there is a lack of large, controlled, randomized human trials supporting the beneficial claims. Thirdly, the harsh conditions of the gastrointestinal tract can impede the delivery of probiotic bacterial cells. One significant advantage of using prebiotics as opposed to probiotics is that they overcome the viability issue. Prebiotics are, by definition, not hydrolyzed by enzymes during

gastrointestinal transit and, therefore end up being available to stimulate selective growth of gut microbiota. Nevertheless, it is hardly possible to demonstrate the selectivity criterion of prebiotics. On the contrary, microencapsulation of probiotic bacteria is a delivery method that overcomes the viability issue and is also selective.

Therefore, it is easy to envisage that microencapsulated probiotics may soon be available on the market, and research in the long term may focus on developing formulations combining microencapsulated probiotics, prebiotics and/or antibiotics. The main challenge is developing suitable models to characterize and understand the microbiota, and developing effective treatment formulations, such as targeted delivery of probiotics within the gastrointestinal tract.

Towards new models of human gut microbiota

In vitro models of the human microbiota are essential to screen, characterize, develop, and perform mechanistic studies under controlled parameters. To test the therapies

being developed effectively, special attention has to be directed to the development and optimization of *in vitro* models of the microbiota, given that these are rare. Models to mimic the whole gastrointestinal tract and specific compartments are essential. The challenge is to create a fermentation system featuring microbial diversity similar to that in the human gastrointestinal tract. Due to sampling complications, the microbiota of a fecal inoculum is assumed to be representative of the intestinal microbiota.¹⁰⁴ The computer-controlled dynamic human gastrointestinal model consists of a succession of five vessels: the stomach, the small intestine, and the ascending, transverse, and descending colon (Figures 5A and 5B).^{105,106} Temperature, pH, and anaerobic parameters are all controlled using Labview® software. The system is equipped with portholes for the addition of medium, the removal of spent culture, and

the administration of therapeutics. Attention is also needed to simulate the bacterial microhabitat of the intestines, because the metabolism and functioning of the mucosal-associated microbiota differ from those free-living in the lumen.¹⁰⁶ Efforts should be made to understand the effect of gastrointestinal tract adhesion of bacterial cells on bacterial metabolism by designing a model to investigate adhesion of probiotics for gut microbiota modulation.

Microencapsulation to boost efficacy of probiotic treatment

There are many methods for microencapsulation of bacterial cells available, and these can be effectively used in boosting probiotic oral delivery and clinical efficacy. Our research interest is mainly focused on the customization of a myriad of microencapsulated probiotic formulations

Figure 5 Computer-controlled dynamic human gastrointestinal (GI) model used for studies on the human gut microbiota. A) Schematic representation, B) photograph. Vessels in series representing stomach, small intestine, ascending colon, transverse colon, and descending colon. All vessels can be continuously magnetically stirred; temperature can be controlled by the flow of hot water in the double jacketed vessel. Food can be given at a time interval and samples can be collected from any GI part at any time (eg, spent removal of the spent culture at defined intervals). This also allows for the administration of biotherapeutics, control of pH, enzyme, anaerobic atmosphere and other GI parameters effecting gut microbiota..

using polyelectrolyte complexation, a widely used technique based on the interaction of oppositely charged polymers that form a physical membrane around the probiotic.^{99,105–111} The physicochemical properties of the capsules are engineered to guarantee survival of the bacteria, appropriate diffusion of metabolites and substrates, and targeted delivery. In gastrointestinal tract simulators, the enzymatic activity, stability, and viability of microencapsulated probiotics have been demonstrated.^{105–109} Results confirm the potential of orally delivered microencapsulated bacteria to manage hypercholesterolemia, hypertriglyceridemia, and colon cancer.^{108,111} For microencapsulated probiotics to be marketable, research must be directed at developing structural and functional models of the microbiota to test the therapeutic formulations. Finally, in vivo models should evaluate the efficacy of microencapsulated probiotic formulations while characterizing preclinical cellular and tissue responses. The potential of microencapsulated *Lactobacillus fermentum* to lower cholesterol and triglycerides in Bio F(1)B hamsters fed a hypercholesterolemic diet was investigated.¹⁰⁸ Treatment with the bacterial formulation reduced total cholesterol, low-density lipoprotein cholesterol, and triglycerides, and also reduced the progression of atherosclerotic lesions. The antitumorigenic properties of microencapsulated probiotics in multiple intestinal neoplasia were also investigated in mice carrying a germline APC mutation.¹¹¹ Oral administration of microencapsulated *Lactobacillus acidophilus* resulted in suppression of colon tumor incidence, multiplicity, and size. Preclinical trials confirm the potential of orally delivered microencapsulated probiotics for managing hypercholesterolemia, hypertriglyceridemia, and colon cancer.

Conclusion

This is an extensive and timely review of the gut microbiota and its role in human health and disease. First described are the key players among the microbiota, how they develop into a network in the gastrointestinal tract, their roles in various gastrointestinal and other diseases, methods to study human gut microbiota, and associated health benefits and limitations. Interest in the microbiota arose after the realization that an altered balance in the gut could lead to disease. By using probiotics, prebiotics, and antibiotics, one can tune the composition of the gut to improve the health of the host. Optimization of methods to modulate and characterize the microbiota and probiotics still remains to be done. The microbiota itself can allow for the analysis of health, and biomarkers of a given microbiota can be indicative of disease.

Although preliminary, two animal models have shown that microbial metabolism is correlated with specific patterns of metabolites excreted in urine.¹¹² This could potentially be a significant breakthrough in the new realm of personalized medicine.

Gut microbiota is an area of research with potential for pure scientific exploration with significant biotherapeutic applications. It remains largely unexplored. This is due to the complexity of the microbiota and the difficulties in collection and analysis of data. In addition, lack of understanding of the role of bacterial cells in human health and lack of well defined clinical trials on known beneficial probiotics, other bacterial cells, and associated systems, such as delivery systems, are seriously hampering this very important area of biological therapy. Development of cutting-edge technologies for understanding human gut microbiota, their manipulations, and screening and development of cutting edge formulations for probiotic delivery, such as microencapsulation, are strongly needed, along with accurate in vitro models.

Highlights

The human gut microbiota is an asset for human homeostasis.

- The human gut microbiota, which resides within the gastrointestinal tract system, is composed of trillions of microorganisms with tremendous diversity and complexity
- The gut microbiota should be considered as a vital organ, carrying essential metabolic, protective, and structural/histological functions in maintaining body homeostasis, human health and other manifestations
- An altered composition of the intestinal ecosystem, a state called gut dysbiosis, can lead to physiological changes in the intestinal environment, disrupting the functions of the gut microbiota, autoimmune, allergic, metabolic and alcoholic liver diseases, irritable bowel syndrome, colorectal cancer, and bacterial infections have all been linked to gut dysbiosis
- Bacterial imbalances can be responsible for immunological deregulation, breakdown of colonization resistance, induction of systemic endotoxemia, production of carcinogenic compounds and alteration of energy and lipid metabolism
- Due to the inherent plasticity of the gut microbiota, therapeutics such as probiotics, prebiotics, and antibiotics are used to modulate the human intestinal ecosystem to obtain better human health

- Major efforts should be directed towards development of in vitro and in vivo models to understand the human gut microbiota and explore development of biotherapeutic possibilities and methods, such as microencapsulation, for suitable delivery of beneficial bacterial cells to the gastrointestinal tract and other systems for human health.

Biologics: Targets & Therapy

Publish your work in this journal

Biologics: Targets & Therapy is an international, peer-reviewed journal focusing on the patho-physiological rationale for and clinical application of Biologic agents in the management of autoimmune diseases, cancers or other pathologies where a molecular target can be identified. This journal is indexed on PubMed Central, CAS, EMBase, Scopus

Submit your manuscript here: <http://www.dovepress.com/biologics-targets--therapy-journal>

Dovepress

and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
