Abstract: Improved diagnosis and treatment regimens have resulted in greater longevity for men with prostate cancer. This has led to an increase in both androgen deprivation therapy (ADT) use and duration of exposure, and therefore to its associated adverse effects, such as sexual dysfunction, osteoporosis, reduced muscle mass, increased fat mass, and increased incidence of cardiovascular disease and type 2 diabetes. Given that the adverse effects of ADT are systemic, often debilitating, and difficult to treat, efforts continue in the development of new strategies for long-term management of prostate cancer. The PubMed database was searched to select trials, reviews, and meta-analyses in English using such search terms as “prostate cancer” and “androgen deprivation therapy”, “cardiovascular risk”, “lean body mass”, “exercise”, and “diet”. The initial searches produced 379 articles with dates 2005 or more recent. Articles published after 2004 were favored. This review utilizes the latest data to provide a status update on the effects of exercise and diet on patients with prostate cancer, focusing on ADT-associated side effects, and it discusses the evidence for such interventions. Since the evidence of large-scale trials in patients with prostate cancer is missing, and an extrapolation of supporting data to all patient subgroups cannot be provided, individualized risk assessments remain necessary before the initiation of exercise and diet programs. Exercise, diet, and nutritional supplementation interventions have the potential to provide effective, accessible, and relatively inexpensive strategies for mitigating ADT-associated toxicities without introducing additional adverse effects. **Keywords:** androgen deprivation therapy, ADT, diet, exercise, nutrition, prostate cancer, dietary supplements

Introduction

Prostate cancer is the most frequently diagnosed cancer among men in developed countries.¹ Widespread adoption of programs to screen for prostate-specific antigen has revolutionized the diagnosis and treatment of prostate cancer. Early detection and development of new treatment options have improved outcomes, increasing 5-year survival from 67.8% to 99.7% over the past 25 years, with 10- and 15-year survival presently at 99% and 94%, respectively.² Thus, prostate cancer has moved from an aggressive, often fatal, disease to a chronic condition requiring comprehensive management strategies to maintain patients' quality of life (QoL).

Androgen deprivation therapy (ADT) has long been the frontline treatment for advanced prostate cancer.^{3–8} Indeed, over a third of the roughly 3 million men in the USA presently diagnosed with prostate cancer have received or are receiving ADT.² Although ADT has been found to improve the overall survival, it is also associated with

adverse side effects, including sexual dysfunction, gynecostasia, hot flashes, osteoporosis, cognitive defects, reduced muscle mass, increased fat mass, and increased incidence of both cardiovascular disease and type 2 diabetes.⁹⁻¹²

Although earlier diagnosis and treatment have greatly extended patient longevity, they have also led to a considerably longer duration of ADT. An alternative, intermittent ADT has been proposed to mitigate the adverse effects of continuous ADT with the premise that it will not impact efficacy.^{13,14} Although intermittent ADT offers some relief from the side effects of continuous ADT, in particular during treatment pauses, comprehensive management plans aimed at helping patients cope with the long-term effects of ADT throughout all phases of therapy are essential, but are often missing.

Ninety percent of the patients with prostate cancer in the USA are aged 60 years or older,² a population known to be at high risk for cardiovascular and diabetic comorbidities.¹⁵ Exercise and diet programs are important factors in reducing the risks of these conditions.¹⁶ Exercise and improved diet, therefore, have the potential to improve the QoL and also possibly the long-term survival of patients with prostate cancer (who may or may not be on ADT).^{17,18} Some clinical trial data, including that from multiple randomized controlled trials, have demonstrated the ability of exercise and dietary modifications to ameliorate ADT-associated adverse effects, and patients and physicians need to be informed about these nonpharmacologic approaches. Here, we review recent studies of exercise and nutritional interventions to assess their potential impact on the outcomes in patients with prostate cancer receiving ADT.

We searched the PubMed database to select trials, reviews, and meta-analyses in English in the last 10 years (2005–2015) using search terms “prostate cancer and cardiovascular diseases/diet/exercise/sexual dysfunction”, “androgen deprivation therapy and diet/exercise/bone”, and “cancer and body composition”. The initial searches produced 3,863 records after the removal of duplicates. Figure 1 shows the flowchart of manuscript selection.

Impact of exercise on patients with prostate cancer

Exercise, prostate cancer, and mortality risk

The beneficial impact of regular physical activity on many chronic ailments, including cardiovascular disease, osteoporosis, diabetes, obesity, fatigue, and depression, has been

reported in many studies, not least in the 1996 US Department of Health and Human Services Report of the Surgeon General.¹⁶ There is a paucity of good data with respect to the effect of exercise on the mortality of men with prostate cancer. Studies of cancer (including prostate cancer) have shown that there is a link between increased physical activity and improved physical functioning in cancer survivors. For example, the Reach out to Enhance Wellness study enrolled 641 elderly (mean age, 73 years), sedentary, overweight, or obese (mean body mass index [BMI], 29 kg/m²) cancer survivors (including 94 prostate cancer survivors) and utilized a home-based diet and exercise intervention. The Reach out to Enhance Wellness intervention consisted of workbooks, equipment, and quarterly newsletters, endorsing 15 minutes of strength training every other day and 30 minutes of endurance exercise daily to evaluate the effects on physical function. The intervention produced a decrease in the rate of physical function decline, according to various self-reported measures, including the Medical Outcomes Study Short Form-36 (SF-36); the intervention also produced a decrease in BMI compared with the control (delayed intervention) population.^{19,20}

Kenfield et al¹⁷ studied a population of 2,705 male health care professionals (mean age at prostate cancer diagnosis about 70 years) with nonmetastatic prostate cancer and found that those participating in vigorous physical activity (metabolic equivalent task [MET] value²¹ ≥ 6) for a duration ≥ 3 hours/week demonstrated a 49% lower risk of all-cause mortality and a 61% lower risk of death specifically from prostate cancer, compared with men who did < 1 hour/week of vigorous activity. MET value is a way of defining the energy cost of physical activity in adults, and examples range from meditation (1 MET), stationary bike or jogging (7 METs), playing squash (12 METs), running up stairs (15 METs) to running at 14 mph (25 METs).¹⁷ The men engaging in nonvigorous exercise (MET value < 6 , eg, walking at a normal to very brisk pace) ≥ 90 minutes/week had an all-cause mortality risk 46% less than those who walked < 90 minutes/week. There was, however, no statistically significant difference between nonvigorous exercise and walking with respect to prostate cancer-specific mortality.¹⁷ Other studies in large populations of men who were cancer-free at enrollment, however, have shown no significant association between physical activity, body weight, and waist girth and prostate cancer risk,^{22,23} although Patel et al²³ suggest that physical activity may be associated with reduced risk of aggressive prostate cancer.²³

Abbreviation: ADT, androgen deprivation therapy.

Strength, lean body mass, and functional ability

A systematic review of ten studies (five randomized and five uncontrolled clinical trials) examined the effects of exercise on patients receiving ADT.²⁴ Study populations included both patients with metastatic and nonmetastatic prostate cancer, with mean ages ranging from 63 to 72 years, and with ADT duration of 4 to >44 months. The number of patients on ADT undergoing exercise interventions ranged from five in a pilot study²⁵ to 74.²⁶ Although most interventions included two to six exercise-based sessions per week for 24 weeks, the interventions were heterogeneous, varying in duration, frequency, intensity, and degree of supervision. Despite this heterogeneity, the evidence demonstrated that physical performance was improved by exercise. Randomized controlled

trials found exercise to be consistently beneficial for muscular performance: reported as increases in muscular strength and increases in upper and lower limb strength, compared with the control population (see, eg, Bourke et al²⁷ and Galvão et al²⁸). Although one study found improvement in cardiovascular fitness²⁷ and others showed improvements in 400-m²⁹ or 6-minute walk times,²⁵ still other studies showed no improvement in 6-minute walk times or in cardiorespiratory fitness.^{30,31}

Body composition is a component of many studies investigating exercise effects on prostate cancer patients on ADT,²⁴ and resistance training has been shown to either increase lean body mass²⁸ or reduce its decline²⁶ in randomized controlled trials. Other uncontrolled studies have shown increased lean body mass,²⁹ decreased BMI, or decreased weight with resistance exercise.^{29,32} The data on adiposity are not clear,

as some studies report an adiposity reduction,^{30,33} whereas others report no differences between exercising and control groups.^{26–28}

Fatigue

Fatigue measurements, assessed by patient-reported questionnaires, such as the Functional Assessment of Cancer Therapy-Fatigue (FACT-F)³⁴ or the Functional Assessment of Chronic Illness Therapy-Fatigue,³⁵ are frequently assessed together with exercise outcomes in these studies.^{24,36,37} In general, the evidence is equivocal as to whether exercise helps diminish patient-reported fatigue. Some studies show clinically meaningful improvement versus controls,^{26,27,33,38} whereas another failed to show benefit.³⁰ Some uncontrolled studies show benefit; for example, Hanson et al²⁹ showed that in 17 black men on ADT, strength training reduced fatigue perception by 38%, which exceeds changes reported in other cancer survivor studies. On the other hand, for example, Hansen et al²⁵ found that exercise training in ten men with prostate cancer produced no significant difference in fatigue between those on ADT and those who were not. Neither of these studies was large enough to allow statistically meaningful comparisons to be made between the groups.

QoL

Many controlled and uncontrolled studies report that physical activity improves aspects of patient-reported QoL. The most widely used measures for self-reported general and psychosocial QoL (mental health/emotional well-being) are the Medical Outcomes Study 12-item Short Form (SF-12) and the SF-36.^{24,39} A 3-month exercise program consisting of aerobic and resistance exercises produced clinically significant improvement in the SF-36 scores of 32 men with prostate cancer starting ADT, compared with 31 men starting ADT on usual care but not exercising.³⁸ Likewise, in a pilot study, resistance exercise training sessions three times a week for 12 weeks produced clinically significant prostate cancer-specific improvement in the QoL for five men on ADT, compared with those on usual care, as measured by the FACT-Prostate scale.²⁵ In contrast, however, Cormie et al³⁶ studied 20 men with bone metastases secondary to prostate cancer and found no significant between-group differences in QoL or psychological distress comparing those who underwent a 12-week resistance exercise program and those on usual care.

Interestingly, a study of 66 prostate cancer survivors compared home-based aerobic training with home-based

resistance training and found that after 6 months, the aerobic group had undertaken significantly more physical activity than the resistance training group, although fatigue and QoL were not significantly different between the two groups.³¹ This suggests that aerobic exercise may be more attractive to the prostate cancer population than resistance exercises. This has implications as aerobic exercise is anticipated to have a greater impact on cardiovascular health, whereas resistance exercise is more associated with increases in muscular strength and lean body mass.

Cardiovascular disease

In 2006, the Surveillance, Epidemiology, and End Results Medicare study reported an observed 11% increase in myocardial infarction risk and a 16% increased risk of coronary heart disease and death from cardiac arrest in an observational study of prostate cancer patients receiving ADT, versus those not on hormone therapy (n=73,196).³ In a later study of men in the Veterans Healthcare Administration database, ADT was also found to be associated with stroke.⁴⁰ These reports, along with observational evidence from several additional studies linking ADT to an increased risk of cardiovascular events, prompted the US Food and Drug Administration to issue a communication in 2010 requiring that manufacturers of drugs for ADT include a warning label citing an increased risk of diabetes and certain cardiovascular diseases (eg, heart attack, sudden cardiac death, and stroke) with their use.⁴¹ The link between ADT and cardiovascular events remains somewhat controversial; however, as subsequent studies indicate that although ADT appears to be linked to an increased risk for cardiovascular events, it is not associated with higher rates of related mortality.^{11,42}

Although there are no studies to date that are specifically powered to evaluate the effect of exercise on ADT-mediated cardiovascular events, there is a large body of evidence supporting the role of physical activity in the prevention and management of cardiovascular disease in broader populations.^{43–46} Many plausible mechanisms could be involved in the protective effects of physical activity, including protection against atherosclerosis, improvement of plasma lipid and lipoprotein profile, dilation of peripheral blood vessels/attenuation of sympathetic nervous activity leading to reduction in blood pressure, adaptations to coronary circulation, reduction in thromboses due to enhanced fibrinolysis, and decrease in the aggregation and adhesion of platelets.^{16,47,48} By extension, it seems likely that implementation of an exercise program would help mitigate the cardiovascular risk factors associated with ADT, although further research is necessary.

Bone health

Bone density reduction is a serious consequence of ADT, with the frequency of osteoporosis and osteopenia being directly proportional to treatment duration.^{49–51} This is particularly significant in men, as a high mortality rate (up to 37.5%) is associated with minimal trauma fractures.⁵² The greatest loss of bone mineral density occurs in the first year of ADT, with noticeable changes seen within months as androgen levels decline.⁵³ Many epidemiologic studies have reported that low body weight and low BMI are risk factors for diminished bone mineral density and fragility fracture. An explanation for the correlation of higher body weight and bone resilience is that this may be due to increased mechanical load on the bones in heavier persons stimulating an increase in bone mineral density.^{54,55} There is considerable evidence that physical activities involving mechanical loading, such as resistance training and high-impact load-bearing exercises, are beneficial for bone health in the general population.^{16,52} In contrast to this view, however, a recent study of a heterogeneous cohort of 8,833 men aged 18–64.9 years used computed tomography to show an inverse relationship between adiposity (BMI and visceral and subcutaneous adiposity) and bone quality.⁵⁶

Despite the known effects of ADT on bone health, there is a paucity of data available regarding the impact of exercise on the bone health of patients receiving ADT. Recently, a randomized controlled study in 63 men with prostate cancer examined the effect of moderate- to high-intensity aerobic and resistance exercises in preventing ADT-associated toxicity in the first 3 months of treatment and found no significant difference in bone mineral density loss and in blood biomarkers of bone turnover between the exercise and usual care groups.³⁸ The authors speculated that the efficacy of exercise-based interventions will likely require incorporation of targeted, high-impact activities that provide skeletal loading, such as jumping and hopping. Indeed, similar results have been observed in resistance training studies in older men and women, where only high-intensity, and not moderate-intensity, strength training resulted in increased bone mineral density.^{57–59}

A clinically important issue is whether high-impact or moderate- to high-intensity exercise might put patients with prostate cancer at risk of fracture, particularly in 70%–80% of advanced prostate cancer patients who have bone metastases.⁶⁰ The risk increases further given the effect that ADT has on bone health. For example, a study of 19,079 Canadian men with prostate cancer demonstrated a 65% increased fragility risk for those on at least 6 months of ADT, compared with those not on ADT.⁶¹ Exercise, therefore, is commonly

not recommended for this population, due to fears over fragility and potential fracture. However, a recent randomized, preliminary, 12-week study of targeted, moderate- to high-intensity exercise in 20 prostate cancer patients with bone metastases, found that the exercise was well tolerated, with 93% patient compliance and no reported adverse events.³⁶ This provides initial evidence that supervised resistance exercise may be safe for prostate cancer patients with metastatic bone disease, although the data from this trial showed that the intervention made no significant changes to the patients' bone mineral density. The supervised exercise did, however, improve other measures, such as physical activity, muscular strength, and lean body weight. More studies involving larger numbers of subjects are required to build on these results.

Sexual dysfunction

About 30%–90% of prostate cancer patients have been reported to experience adverse sexual side effects from their care treatments.^{62–64} Sexual dysfunction can profoundly affect patients' QoL and lead to depression, loss of connection with their partner, and decline in their identity as a man.^{62,64} Addressing ADT complications will likely play an important role in improving the overall outcomes.

Kratzik et al⁶⁵ observed that in healthy men aged 45–60 years ($n=674$), risk of severe erectile dysfunction was 83% less among men who exercised $\geq 3,000$ kcal/week, compared with those who exercised $\leq 3,000$ kcal/week. In two studies, Cormie et al^{38,66} examined the effect of moderate- to high-intensity exercise (resistance and aerobic) over a 12-week intervention. Using the sexual function section of the European Organization for Research and Treatment of Cancer prostate cancer-specific module questionnaire, the researchers found significant differences between the usual care (nonexercise) group and the exercise group, with the latter reporting maintenance of sexual activity and a higher percentage of participants with a major interest in sex (17.2% vs 0%, $P=0.024$).^{38,66} In-depth interviews with 18 men (mean age, 63.1 years) receiving ADT for prostate cancer suggest that exercise may be helpful in alleviating sexual dysfunction in a broader, less specific manner. The role of exercise in mitigating the reduction in lean body mass and muscular strength seen with ADT may be important in improving the subjects' perceptions of their masculinity, which in turn leads to a better psychological frame of mind with respect to their sexuality.⁶⁷ Further research is needed, but this preliminary data suggest that exercise may be able to play a role in reducing ADT-associated sexual dysfunction.

Metabolic syndrome

ADT is associated with significant adverse metabolic effects, including elevated serum triglycerides (≥ 150 mg/dL); fasting serum glucose ≥ 100 mg/dL; weight gain, especially of the abdomen; peripheral insulin resistance; and increased diabetes risk.^{3,9,40,68} These effects are characteristics of metabolic syndrome and increase the risk of heart disease and stroke, in addition to diabetes.⁶⁹

We reviewed the data on cardiovascular fitness earlier, and there is good evidence that exercise improves or mitigates the decline in lean body mass and decreases the BMI of patients on ADT. There is also the additional evidence that exercise may impact the overall all-cause mortality, of which cardiovascular events are a large proportion. Exercise that is considered desirable in a noncancer population is also likely to show benefit in men with prostate cancer. Segal et al²⁶ reported that 12 weeks of resistance training in 155 men with prostate cancer and receiving ADT resulted in significantly greater upper and lower body muscular fitness, compared with those on usual (nonexercise) care; however, waist circumference, BMI, or subcutaneous adiposity differences between groups were not significant.

Recently, two studies^{38,70} have shown that exercise-based interventions are promising methods for reducing few ADT-specific metabolic effects. Results from a randomized pilot study assessed the impact of over 6 months of combined metformin, a low-glycemic-index diet, and exercise in 20 prostate cancer patients at ADT initiation and compared this with 20 men who were on ADT alone. The metformin and exercise group had decreased abdominal girth, weight, BMI, and systolic blood pressure, compared with the group on ADT treatment alone, although insulin-resistant biochemical markers were not significantly different. In this small study, however, it was not possible to separate the metformin and dietary effects from the exercise components.⁷⁰ In the study by Cormie et al³⁸, 63 prostate cancer patients were randomized to receive either a 3-month aerobic and resistance exercise program or usual care, concomitant to initiation of ADT. Patients receiving the exercise-based intervention demonstrated significant reductions in ADT-associated metabolic effects, including decreased whole body fat mass, trunk fat mass, and percentage fat, compared with the usual care control group. The ratio of total cholesterol to high-density lipoprotein (HDL) cholesterol improved in the exercise group, which is clinically significant, as this ratio is a common cardiovascular disease risk marker. There were no significant changes, however, in other cardiovascular and metabolic biomarkers, such as triglycerides, insulin and glucose levels, or glycated hemoglobin.³⁸

Evidence from trials has also shown that ADT can cause significant increases in HDL.^{38,71–73} A feature of ADT-associated metabolic changes is that HDL is usually elevated, which is not typical with metabolic syndrome (where HDL levels are low).^{72,73} Potentially, HDL increases could be further amplified by the addition of prescriptive exercise. Although these are preliminary studies, they suggest that exercise may provide some benefit in lessening the adverse metabolic effects of ADT. Two randomized trials are presently being conducted to investigate this further.^{74,75}

C-reactive protein, an inflammation marker commonly elevated in metabolic syndrome, showed a clinically meaningful reduction in a randomized controlled trial of exercise in 57 men on ADT.²⁸ Going forward, further study is required to investigate the correlations between C-reactive protein level and exercise.

Although the final verdict from large-scale trials is still outstanding, exercise programs should be considered an integral part of treatment for men with prostate cancer, as they can provide low-cost, scalable, and widely accessible strategies to help counter the systemic effects associated with prostate cancer therapies, including ADT. Exercise impacts patient well-being, both physical and psychological, potentially leading to improved physical functioning and survival.^{24,39,75–77} However, before a general recommendation can be issued, treating physicians should exercise caution when considering to institute exercise and diet programs, and patients should be carefully assessed prior to any intervention.

Effect of nutrition and dietary supplements on the complications of ADT

Nutrition and dietary supplements

There is a lack of data on how nutritional adjustments might affect ADT-associated adverse effects and the few studies that have investigated the integration of either nutritional counseling or modified diet have done so in conjunction with another intervention, making it difficult to specifically assess the impact of dietary changes.^{70,78} Given the similarities to what is observed in postmenopausal women, however, some researchers have made specific recommendations for lifestyle modifications, including smoking cessation, moderation of alcohol and caffeine intake, and supplementation with vitamin D and calcium.^{79,80} As mentioned in the previous section, a low-glycemic-index diet, regular exercise, and metformin treatment have been shown to significantly improve abdominal girth, weight, BMI, and systolic blood pressure in patients receiving ADT.⁷⁰ Caffeine is also garnering research as a method to potentially improve workout energy levels and

duration and postworkout discomfort.⁸¹ Studies with prostate cancer patients are lacking, although caffeine consumed (0.16 mg/kg anhydrous caffeine) 1 hour before completing a number of functional performance and exercise capacity tests has been reported to increase the exercise capacity by 3.0% versus placebo in a randomized, double-blind crossover study in 30 prostate cancer survivors. There was no significant difference, however, in postexercise fatigue and perception of exertion compared with placebo, nor in other functional performance measures.⁸²

Bone health

Despite the debilitating effects of osteoporosis observed in men receiving ADT, few studies have examined two key modulators of bone health in this population: vitamin D and calcium. Bone density deterioration is known to occur shortly after initiation of ADT.^{49,50} A meta-analysis of calcium and vitamin D studies in women and men aged ≥ 50 years (92% of study participants were women and those with secondary osteoporosis were excluded) provided evidence that calcium and vitamin D supplementation is associated with a reduced rate of bone mineral density loss in the hip and the spine, and also with decreased risk of fracture.⁸³ On the basis of this evidence, the European Association of Urology has recommended that calcium and vitamin D supplements be monitored both prior to and during ADT if serum concentrations fall below the lower limit of normal (normal range: calcium, 2.2–2.6 nmol/L; vitamin D, 100–160 nmol/L).⁸⁴ In its most recent guidelines, the European Association of Urology recommends that a daily intake of $\geq 1,200$ mg/day of calcium and 1,000 IU of vitamin D may be useful for improving bone mineralization in prostate cancer patients.⁸⁴ The National Osteoporosis Foundation, on the other hand, supports the Institute of Medicine guidelines recommending that men aged 50–70 years consume 1,000 mg/day of calcium, and those ≥ 71 years, 1,200 mg/day of calcium.^{85,86}

A systematic review of twelve clinical trials, however, failed to find conclusive support for these recommendations in prostate cancer patients receiving ADT, noting that the frequently recommended daily doses of calcium (500–1,000 mg) and vitamin D (200–500 IU) were insufficient to prevent ADT-associated bone density loss.⁸⁷ More recently, in a prospective longitudinal study, Alibhai et al⁸⁸ examined the long-term effects of calcium and vitamin D supplementation in 160 prostate cancer patients (mean age, 69 years), with and without ADT. Vitamin D, but not calcium, was shown to provide some protection from bone density loss, especially in the first year of ADT. It seems likely that the efficacy of vitamin D and calcium supplementation may require implementation

of concomitant exercise programs to stimulate bone accrual, as discussed earlier.^{36,38,75}

Fat and muscle mass

Although there are a number of randomized controlled trials that have demonstrated exercise to be effective for reducing fat mass in overweight older men,⁸⁹ the absence of testosterone in men on ADT has proven to be a more difficult challenge. It has been reported that during the early phase of ADT, fat loss or maintenance of BMI can be achieved through exercise alone.^{38,90} This concept remains controversial, however, as other studies have suggested that, in addition to exercise, caloric restriction is required for consistent fat loss in men.^{89,91}

Loss of muscle mass, which has major consequences for physical function and risk of metabolic disease, is a frequently reported adverse effect of ADT.¹¹ Resistance training has consistently been associated with muscle hypertrophy in men on ADT.^{28,31} This effect is likely to be amplified by appropriate nutritional supplementation, including protein, carbohydrates, and creatine monohydrate, as has been demonstrated in studies of both younger and older men not on ADT.⁹² Recently, a meta-analysis of 14 randomized controlled trials in a total of 626 adults showed an increase in weight loss, lean body mass, and a decrease in visceral fat among men receiving supplemental whey protein in combination with resistance training.⁹³ Although more studies are needed, the potential for whey protein or another similar protein isolate to mitigate the adverse effects of prostate cancer therapies is considerable.

Fatigue

Encouraging data from a randomized, double-blind, phase III trial of American ginseng (2,000 mg/day) found a statistically significant and clinically meaningful decrease in cancer-related fatigue in 171 patients (4% of whom had prostate cancer), compared with 170 patients on placebo.⁹⁴ The primary endpoint was the Multidimensional Fatigue Symptom Inventory-Short Form. American ginseng is the first treatment option, besides exercise, to show efficacy in addressing cancer-related fatigue, as no other drugs, including stimulants, have been proven to be effective. Interestingly, similar to what was observed with exercise,³⁸ greater benefits were found in patients who started ginseng at the same time as their cancer treatment, compared with patients who started ginseng after treatment initiation. This suggests that treatment with American ginseng should be started at the same time or prior to ADT initiation; however, this needs to be confirmed with a larger study population of patients with prostate cancer.

Cardiovascular disease

The impact of ADT on cardiovascular disease development and progression remains contested in the literature. Regardless, heart disease is a leading cause of mortality in all men, including those on ADT.⁴² Lifestyle changes, such as modifications to diet and exercise, may significantly affect cardiovascular disease risk in prostate cancer patients on ADT.¹⁸

Although it has not been studied in patients on ADT, fish oil has been approved by the Food and Drug Administration for use in lowering triglycerides.⁹⁵ Correspondingly, the American Heart Association recommends that individuals with heart disease take 1,000 mg of eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), the primary omega-3 fatty acid components of fish oil, daily.⁹⁶ Indeed, a large, randomized controlled trial (Japan EPA Lipid Intervention Study) in 18,645 Japanese subjects has shown synergistic effects between omega-3 acids and statins in reducing serum triglycerides in

patients with high cholesterol.^{97,98} Interestingly, further subgroup analysis found that fish oil significantly reduced the incidence of coronary artery disease in subjects with impaired glucose metabolism (–22%), even greater than that observed for subjects with normal glucose metabolism (–18%).⁹⁷

Conclusions

The advent of prostate-specific antigen screening programs, greater public awareness of prostate cancer, and improved treatment regimens have fundamentally altered the disease landscape. A consequence of greater patient longevity is a more extended exposure to ADT and its associated adverse effects. Given that the adverse effects of ADT are systemic, often debilitating, and difficult to treat, efforts are being made in the development of new strategies for long-term management of prostate cancer.

As summarized in Table 1, exercise, diet, and nutritional supplementation interventions have the potential to provide

Table 1 Adverse effects reported with ADT and potential lifestyle, supplemental, and prescription medication solutions

ADT-associated adverse effects	Potential solutions		
	Exercise	Diet	Drugs
Anemia	<ul style="list-style-type: none"> Primarily normochromic, normocytic anemia with ADT, thus no lifestyle or supplemental options available for treatment⁹⁹ Asymptomatic in 90% of patients, so medication is rarely, if ever, needed⁹⁹ 		
Bone loss	Resistance exercise 2–3 times a week in combination with 1,000–1,200 mg of calcium and 800–1,000 IU of vitamin D (from food and/or supplements) ^{36,51,100}		<ul style="list-style-type: none"> Prescription medication should be considered based on the duration of ADT and documented severity of bone loss
Fatigue	Resistance exercise ^{24,38}	<ul style="list-style-type: none"> Caffeine from beverages (general stimulant)⁸¹ American ginseng (2,000 mg/day at 3%–5% ginsenosides)⁹⁴ 	
Hot flashes	Maintaining a healthy weight may reduce the severity of vasomotor symptoms and moderate aerobic exercise could also be beneficial	No dietary supplement has demonstrated a consistent benefit over placebo ¹⁰¹	<ul style="list-style-type: none"> Prescription medication can be effective (eg, megestrol acetate, venlafaxine) for moderate-to-severe QoL – altering hot flashes¹⁰¹
Lipids and/or prediabetes (elevated cardiovascular risk)	<ul style="list-style-type: none"> ADT has controversial cardiovascular risk data¹⁸ Diet and exercise⁸⁰ Abnormal glucose levels may respond to diet and exercise⁷⁰ 	Omega-3 fatty acids (EPA/DHA; 500 mg/dL or more) FDA-approved for hypertriglyceridemia only (although studies lack clinical endpoints) ^{95–98}	<ul style="list-style-type: none"> When appropriate, low-dose statin and/or ezetimibe prescription treatment; low-dose aspirin for those who qualify, based on overall cardiovascular risk⁸⁰ When appropriate, prescription metformin has preliminary data with ADT⁷⁰
Sarcopenia	Resistance exercise 2–3 times per week in addition to calcium and vitamin D recommended daily intake (as for bone loss) ^{28,92}	<ul style="list-style-type: none"> Preliminary indirect evidence suggests that whey protein isolate (or another protein isolate) at 20–25 g per day could also assist with muscle protein synthesis⁹³ 	
Weight gain (visceral adipose tissue accumulation)	Diet and aerobic and resistance exercise ^{24,38}	Whey protein isolate may also assist with appetite suppression ⁹³	<ul style="list-style-type: none"> Metformin (850 mg twice a day) has preliminary data for weight loss with ADT⁷⁰

Notes: Not all the adverse events listed in this table are discussed in this review. We refer the reader to the scientific literature for more detailed discussions of these.

Abbreviations: ADT, androgen deprivation therapy; DHA, docosahexaenoic acid; EPA, eicosapentaenoic acid; FDA, US Food and Drug Administration; IU, international unit; QoL, quality of life.

relatively inexpensive and accessible strategies for mitigating many ADT-associated toxicities and are unlikely to introduce additional adverse effects. However, since the evidence of large-scale trials in patients with prostate cancer is missing, and an extrapolation of supporting data to all patient subgroups cannot be provided, individualized risk assessments remain necessary before the initiation of exercise and diet programs. The coordinated efforts of health care professionals, including exercise physiologists and dietitians, coupled with increased patient awareness, will be critical for effective implementation of such intervention programs, and future research would help to further our understanding of the effectiveness of diet and exercise in this complex patient population.

Research and Reports in Urology

Publish your work in this journal

Research and Reports in Urology is an international, peer-reviewed, open access journal publishing original research, reports, editorials, reviews and commentaries on all aspects of adult and pediatric urology in the clinic and laboratory including the following topics: Pathology, pathophysiology of urological disease; Investigation and treatment of

urological disease; Pharmacology of drugs used for the treatment of urological disease. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/research-and-reports-in-urology-journal>
