

# Pharmacogenetic testing revisited: 5' nuclease real-time polymerase chain reaction test panels for genotyping *CYP2D6* and *CYP2C19*

Jens Borggaard Larsen  
Jan Borg Rasmussen

Laboratory Unit, Danish Epilepsy  
Centre, Filadelfia, Dianalund, Denmark

**Abstract:** Due to their involvement in the metabolism of commonly prescribed psychopharmaceutical drugs, the cytochrome oxidase genes *CYP2D6* and *CYP2C19* are extensive targets for pharmacogenetic testing. The existence of common allelic variants allows the prediction of a metabolic phenotype based on a genotype result, hereby supplying a clinical tool for optimizing prescription and minimizing adverse effects. In this study, we present the development of two 5' nuclease real-time polymerase chain reaction (PCR) test panels, capable of detecting eight of the most clinically relevant alleles of the *CYP2D6* gene (\*2, \*3, \*4, \*6, \*9, \*10, 17, \*41) and the three most common nonfunctional alleles of *CYP2C19* (\*2, \*3, \*4). The assays have been thoroughly validated using a large collection of reference samples, by parallel testing and by DNA sequencing. The reanalysis of reference samples provided the calculation of the frequency of the *CYP2D6*\*4K allele in a population, not previously reported. Furthermore, original test results from *CYP2D6*\*41, generated based on the presence of the 2850T and the lack of the -1584G single-nucleotide polymorphism (SNP), were compared with genotyping based on the current acknowledged founder SNP 2988G of this allele. These results indicate that up to 17.7% of the patients originally tested as carriers of the *CYP2D6*\*41 allele may have had an incorrect phenotypic result assigned. The two 5' nuclease real-time PCR test panels have subsequently been optimized for use in the clinical laboratory, using a standard real-time PCR instrument and software.

**Keywords:** genotyping, 5' nuclease assay, drug metabolism, *CYP2C19*, *CYP2D6*, pharmacogenetics

## Introduction

Interindividual variation in drug response is a common problem in the therapy of psychiatric patients, leading to nonoptimal treatments and potentially serious adverse effects.<sup>1,2</sup> Together with noncompliance, this has a significant impact on the clinical success and hereby also carries social-economic importance.<sup>3-5</sup> This discrepancy is primarily caused by biological variations in uptake, metabolism, and excretion rates, which leads to differences between patients despite having the same or comparable dosages administered.<sup>6</sup> Traditionally, in vivo phenotyping of a patient's drug metabolism capability has been accomplished by administration of selective enzyme substrates, followed by quantification of their metabolic ratio in a matrix like plasma or urine.<sup>6,7</sup> Although such methods hold the benefit of taking all the biological factors into account, hereby giving a direct quantitative measure as the phenotypic result, suitable and specific substrates are not available for all enzyme/protein systems of interest.<sup>6</sup> Also, these methods demand a specifically dedicated clinical setting for their application.

In the last 25 years, the realization that a patient's phenotype for metabolizing a drug can be linked to the genotype of specific enzymes or transporter proteins has led to the development of a range of molecular tests.<sup>8–12</sup> The hypothesis behind these tests is the prediction of a metabolic phenotype based on the genotype, with the overall goal leading to personalized medicine – medicine prescribed based on the genetic information of an individual person.<sup>13,14</sup> The genes that have received the most attention in this context are those of the cytochrome P450 oxidase family (*CYP* genes).<sup>15,16</sup> These genes primarily code for liver enzymes involved in the metabolism and excretion of a wide range of commonly prescribed drugs. Genetic mutations causing decreased or impaired activity of the mature enzyme have been identified and correlated with increased plasma levels of the substrate and adverse effects in patients.<sup>13,17–20</sup> Genetic variations have also been identified causing increased production of an enzyme, and hereby increased metabolism and higher therapeutic levels of prescribed drugs.<sup>21,22</sup>

The most extensively tested cytochrome oxidase genes for clinical purposes are *CYP2D6* and *CYP2C19*.<sup>4,23,24</sup> Both of these genes have nonfunctional variants at a relatively high frequency, causing abolished or decreased metabolism of drugs by the mature enzyme.<sup>25,26</sup> However, while less than a handful of alleles account for almost all poor metabolizers of the *CYP2C19* enzyme, genotyping of *CYP2D6* is much more complex. More than 100 alleles have been identified for this gene.<sup>27</sup> Besides a high number of nonfunctional alleles, an intermediate metabolizer (IM) phenotype also exists having decreased activity compared to the wildtype \*1.<sup>26</sup> Genotyping of *CYP2D6* is further complicated by the existence of pseudogenes (highly homolog genes at the DNA sequence level), the existence of allelic variants generated by hybrid crossovers between *CYP2D6* and *CYP2D7*, and by duplication of the gene in some individuals (copy number variations).<sup>21,28</sup> Because of this, aside from cloning and sequencing that are too expensive for routine use, there is no single molecular method capable of genotyping all identified alleles of the *CYP2D6* and *CYP2C19* genes.<sup>26</sup> Current genotyping techniques therefore focus on the most common clinically relevant alleles. For *CYP2C19*, these are the nonfunctional alleles \*2, \*3, and \*4, while for *CYP2D6*, these include the nonfunctional alleles \*3, \*4, \*5 (gene deletion), and \*6, as well as alleles \*9, \*10, \*17, and \*41 with decreased activity.<sup>29,30</sup> Due to the presence of pseudogenes, the genotyping techniques commonly rely on one of the two approaches: direct detection where the primers in a single polymerase chain reaction (PCR) assay ensure the specificity

to the intended target, or the secondary approach where a primary PCR selectively amplifies the gene/region of interest prior to the actual genotyping assay.<sup>31</sup> The latter method is frequently applied in commercial DNA chip/bead chip-based methods and allows discrimination between higher numbers of alleles.<sup>12,32,33</sup> It ensures less bias generated due to low-quality primers but comes at a higher cost of reagents and specialized equipment, as well as workload in the laboratory.<sup>31</sup> In contrast, direct detection techniques are generally faster, omitting the secondary PCR as well as potential, purification and hybridization steps.

A large range of chemistries have been developed for genotyping both *CYP2C19* and *CYP2D6* using the direct genotyping approach.<sup>34,35</sup> These include probe-based methods (SimpleProbes, HybProbes, TaqMan 5' nuclease<sup>9,36,37</sup>), enzymatic digestion (restriction fragment length polymorphism, RFLP), and high-resolution melting (HRM).<sup>38,39</sup> The quality of all these assays relies on the design of PCR primers specific to the intended target.<sup>26</sup> Given the restriction inferred by the homology to pseudogenes, both primers developed in-house and commercially available ones must be presumed to target the same nucleotide sequences. Therefore, although specific patented techniques or chemistries might apply, the underlying basic design of the PCR primers still governs the quality of the genotyping assay and is the same for published as well as commercial tests. A consequence of this is that with correct validation and optimization, noncommercial assays can significantly decrease the total cost of reagents and hereby the price of genetic tests.<sup>38</sup>

Here, we present two 5' nuclease real-time PCR test panels, capable of identifying eight of the most common *CYP2D6* alleles and three of the most common alleles of the *CYP2C19* gene. The panels have been thoroughly validated and optimized for routine testing. Furthermore, the applied dyes should be compatible with most real-time PCR platforms currently available on the market.

## Method Background

Since 2002, genotyping of *CYP2D6* and *CYP2C19* has been provided as a service by the Laboratory Unit of the Danish Epilepsy Centre. Besides pharmacogenetic tests, the laboratory is also a regional center of Therapeutic Drug Monitoring (TDM). The annual volume of ~300 genetic samples may however still be considered small due to the demographic size of the country. The laboratory participates in a proficiency scheme for *CYP2D6* and *CYP2C19* (<https://www.rfb.bio>), and in addition maintains a program with Diakonhjemmet

Sykehus, Oslo, Norway, where every 6 months, the laboratory exchanges 2×2 samples for confirmation of each other's test performances. Over the years, the applied molecular genotyping techniques used at the laboratory have progressed from primarily RFLP methods using gel electrophoresis to real-time PCR technologies. The original RFLP tests included *CYP2D6* alleles \*2, \*3, \*4, \*5, \*6, \*7, \*8, \*9, \*10, \*11, \*12, \*17, and \*41, as well as the deletion of the alleles \*5, \*13, \*16 and duplication of the alleles \*1, \*2, \*4, and \*41.<sup>37</sup> The *CYP2C19* test consisted of alleles \*2 and \*3. Due to the labor involved in running the initial *CYP2D6* PCR-RFLP genotyping setup, the analysis was performed by selectively excluding individual alleles in a branch-like fashion, based on the presence of common single-nucleotide polymorphisms (SNPs) found in a group of alleles.<sup>24,36</sup> More recently, testing has been done using real-time PCR methods, based on the LightCycler hybridization probes and simple probe technology.<sup>9,35,36</sup>

## Reference material

As reference DNA for validation of the 5' nuclease assays, original test material submitted to the laboratory was used. Upon retrieval, the samples were anonymized and given a laboratory identification number. DNA extraction was performed using the MagnaPure system (Roche Diagnostics, Basel, Switzerland) applying 200 µL of full blood and eluting with 100 µL buffer, resulting in an average yield of 31.1 ng/µL (±9.8 standard deviation) of genomic DNA. Following testing by the original method, extracted DNA was stored at -20°C for up to 5 years prior to its use in the validation of the 5' nuclease assays.

## Assay design

Two alignments of consensus sequences, one of the *CYP2D6* and its pseudogenes *CYP2D7* and *2D8*, and one of the *CYP2C19* with the homolog sequence of *CYP2C9*, were generated ([Supplementary materials](#)). The alignments were used to design specific PCR primers and 5' nuclease probes targeting eight characteristic SNPs/mutations of the *CYP2D6* gene (alleles \*2, \*3, \*4, \*6, \*9, \*10, \*17, \*41; Table 1) and three of *CYP2C19* (alleles \*2, \*3, \*4). Primers were placed into the alignment by visual inspection and located so that they covered heterolog bases between target and pseudogenes ([Supplementary materials](#)). Standard primer and probe design rules were used to ensure their quality.<sup>40</sup> These included a theoretical annealing temperature of 57°C–63°C, 18–25 nt size, and 3' destabilization by minimizing the number of C' and G' in the last five bases. If possible, bases heterolog to

the pseudogene sequences were placed in the 3' end of the primers, and the amplicon size was minimized.

Probes were designed with a theoretical annealing temperature of 8–12°C higher than that of the primers, and with the SNP/mutation located in the center region. A G' immediately adjacent to the 5' labeling was avoided, and the strand containing the most C' in the probe sequence was preferred. Wildtype and mutant probes were further designed, so the maximum difference in the theoretical annealing temperature between them was <1°C.

Before ordering, each primer and probe sequence was validated in silico using the two online software tools Netprimer (Premier Biosoft; <http://www.premierbiosoft.com/netprimer/>) and FastPCR ([primerdigital.com](http://primerdigital.com)).<sup>40</sup> The specificity of primers and probes to their intended targets was confirmed by Primer-Blast search (National Center for Biotechnology Information [NCBI]; [www.ncbi.nlm.nih.gov/tools/primer-blast/](http://www.ncbi.nlm.nih.gov/tools/primer-blast/)). Probes specific for the wildtype sequence were ordered labeled 5' with 6-carboxyfluorescein (FAM) as dye and 3' with black hole quencher-1 (BHQ-1) as quencher, while the mutant probe was labeled 5' with Cal Fluor 540 (a tetrachlorofluorescein [TET] analog; Biosearch, Novato, CA, USA).

## Assay optimization

Primer and probe concentrations for all allele-discriminating assays were optimized using a standard PCR setup on a Bio-Rad CFX connect real-time PCR instrument (Bio-Rad Laboratories, Hercules, CA, USA). The program consisted of 3 minutes of polymerase activation at 95°C, followed by 45 cycles of a collective annealing and elongation step at 60°C for 1 minute (30 seconds for the *CYP2C19* assays), and denaturation at 95°C for 15 seconds. Reactions were performed in a 12 µL volume, consisting of 6 µL Bio-Rad ITaq 2× Universal Probe master mix and 2 µL genomic DNA. For optimization of the primer concentration, a titration series of each pair was prepared going from 200 to 600 nM, with 150 nM of each of the two probes added, and using a heterozygotic sample as template DNA. Optimal concentrations of primers were selected based on the efficiency of the real-time PCR amplification. Presence of unspecific amplification product and primer dimers was investigated by melt curve analysis, using Bio-Rad's High Precision Melting supermix at the same PCR conditions and primer concentrations but without probes added to the reaction mix ([Supplementary materials](#)).

Next, the concentration ratio between the wildtype and mutant probe was optimized for each of the assays. Depending on the observed efficiency at the initial PCR setup with

**Notes:** Comparison between SNPs/mutations detected by the 5' nuclease assays, the AmpliChip P450, and Luminex XTag CYP2D6 kit. Top row shows the list of CYP2D6 alleles identified by the Roche AmpliChip Cytochrome P450 kit (excluding duplications), with their enzymatic activity indicated by color codes: green – normal, yellow – decreased, red – none, and gray – activity unknown. Proposed SNPs/mutations used for the identification of all of the alleles identified by the AmpliChip method are listed on the left side of the table, with the ones included in the 5' nuclease assay highlighted in bold. The presence of each SNP/mutation in alleles is marked by colored squares. Light green indicate mutations only identified by the AmpliChip kit, while blue indicate mutations detected by both the AmpliChip and the Luminex XTag kit. Subtype of an allele that does not contain a given mutation is marked with a “-”, and their letter (e.g., the CYP2D6\*2D is lacking the 1661G>C SNP reported in other CYP2D6\*2 alleles). **Abbreviation:** SNP, single-nucleotide polymorphism

150 nM of each of the probes, the ratio between the two was varied to minimize differences in the fluorescence signal. This was done by lowering the concentration of the more efficient of the two, while increasing or maintaining the concentration of the inferior probe. For each ratio tested, optimization was performed on template DNA from a wildtype homozygote, a heterozygote, and when available a mutant homozygote sample. The probe concentration ratio with the best discrimination capability between each of the tree sample types was selected ([Supplementary materials](#)).

## Validation of the assays

Validation of each assay was done separately on reference material previously tested in the laboratory using the validated RFLP or real-time PCR methods.<sup>9,36,37,41</sup> For each of the 11 assays, 48 genotyped samples were retested: 16 wildtype, 16 heterozygotes, and 16 homozygotes for the mutant allele. For rare alleles, replicates of the same heterozygote and/or mutant homozygote sample were used. This was the case for *CYP2D6* alleles \*3, \*6, \*9, and \*17 and *CYP2C19* alleles \*3 and \*4. Also, since insufficient samples with a heterozygote or homozygote genotype for *CYP2D6*\*10 were available, samples previously tested as carriers of allele \*4 were used for validation of the assay targeting the 100C>T transition (Table 2).<sup>27</sup>

Due to the recent finding of the 2988G>A transition in *CYP2D6*\*41 and its classification as the founder SNP of this allele,<sup>42,43</sup> all archival samples previously designated as carriers of the \*41 allele (n=97) were retested using the 5' nuclease assay. Tests differing from that of the original RFLP assay were validated by parallel testing with Diakonhjem-

met Sykehus, Oslo, Norway. Additionally, sequencing of ambiguous samples was performed at Roskilde University Hospital using a standard Sanger sequencing technique (BigDye 3.1; Thermo Fisher Scientific, Waltham, MA, USA).

## Results

The high sequence homology between the two genes targeted for genotyping in this paper, and their respective pseudogenes (*CYP2D7/CYP2D8* in the case of *CYP2D6* and *CYP2C9* in the case of *CYP2C19*), makes the design of specific PCR primers difficult.<sup>26,28,44</sup> This is especially true for *CYP2D6* where the high number of polymorphisms further puts restrictions on their location in the sequence.<sup>26</sup> For the validation of the 11 assays, a total of 541 retests were performed. Only one sample did not comply with the outcome of the original test result or could not be verified by parallel testing, while another 11 samples failed to amplify, most likely due to degradation of DNA during storage.

## CYP2C19 assays

Although it encodes a protein similar in size, the gene of *CYP2C19* is >80,000 nt longer than that of *CYP2D6*. Also, while *CYP2D6* has two pseudogenes, only *CYP2C9* shows strong sequence resemblance to *CYP2C19*.<sup>45</sup> This, together with significantly fewer clinically relevant alleles, makes the design of primers and probes generally easier for this gene, compared to *CYP2D6*.<sup>27</sup>

The *CYP2C19* allele \*2 is the most common nonfunctional variant found in Caucasians.<sup>25</sup> The founder SNP is the 19154G>A transition located outside exon 5, which causes a splicing defect of the transcript and hereby abolishment of

**Notes:** This table presents the number of samples tested and the result of the individual validation of each of the 11 5' nuclease assays. Figures to the left are the number of samples used for validating the assay, and right are the number of samples in agreement between the original test and the 5' nuclease assay.

**Abbreviation:** PCR, polymerase chain reaction.

enzyme activity in the protein. A second SNP, 12122G>A, is however also conserved between all nine subtypes currently listed.<sup>27</sup> The primers designed for genotyping *CYP2C19*\*2 span a 211 bp region (Table 3). Specificity is achieved by a two-base difference to the *CYP2C9* sequence in both the forward and reverse primer, of which one base is located within the last 5 nt in the 3' end. In addition, the probes targeting the 19154G>A SNP have a three-base heterogeneity to *CYP2C9*.

The *CYP2C19*\*2 5' nuclease assay was validated on 48 archival samples. These consisted of 16 wildtype homozygotes, 16 heterozygotes, and 16 homozygotes for the mutant SNP 19154A (Table 2). One heterozygote sample failed to amplify, while the result of the remaining 47 samples all complied with that of the original test.

Allele \*3 is the second most common nonfunctional allele of *CYP2C19*. The founder SNP is the 17948G>A that causes premature stop of translation.<sup>27</sup> The primers of the 5' nuclease assay amplify a 271 bp fragment, and each contains four bases different to the corresponding sequence of *CYP2C9* (Table 3).

Since it is present at a considerably lower frequency than *CYP2C19*\*2 in Caucasians, only one heterozygote and no homozygote sample were available for validating the allele \*3 5' nuclease assay (Table 2). For this reason, the single heterozygote sample was tested in triplicate during the validation, together with 45 wildtype homozygote samples. All results of the assay conformed to that of the original test.

The nonfunctionality of *CYP2C19* allele \*4 is due to an A>G transition in the start codon of the gene (1A>G).<sup>27</sup> The allele is rare in Caucasians, where it has been reported at a frequency of 0.003 and is neglectable in Africans and Hispanics.<sup>25</sup> The PCR designed to flank the SNP generates a 256 bp amplicon. Each of the primers ensures specificity to the *CYP2C19* gene based on a two-base heterogeneity, while the forward primer in addition also contains a two-base “-CA-” insert not present in *CYP2C9* (Table 3). For the validation of the assay, six replicate tests of a single available heterozygote sample were used, together with 43 wildtype homozygotes (Table 2). Five of the wildtype samples failed to amplify, while all the other acquired results conformed to that of the original tests.

## CYP2D6 assays

Identification of *CYP2D6*\*2 was previously performed at the Danish Epilepsy Centre, using a SimpleProbe assay targeting the 2850C>T transition, and further exclusion of alleles \*4 and \*41 was based on the result of other tests.<sup>36,37</sup> This SNP is located in exon 6 of the gene, in a region low on other

polymorphisms.<sup>27,44</sup> The same region is however well conserved between *CYP2D6* and its two pseudogenes *CYP2D7* and *CYP2D8*. For this reason, the forward primer of the 5' nuclease assay *CYP2D6*\*2 is located immediately upstream of the exon.<sup>44</sup> Selective amplification of *CYP2D6* by this primer is achieved by spanning a “-CT-” insert that is only present in the sequence of the two pseudogenes (Table 3). Further specificity is obtained by the reverse primer containing one to two bases that are heterolog to the sequence of the *CYP2D7* and *CYP2D8* gene. These bases are located within the last five bases of its 3' end. Together, the two primers generate a 116 bp amplicon (Table 3). The immediate area surrounding the 2850C>T SNP also contains a low degree of polymorphism, and no other SNP of frequently occurring alleles of the *CYP2D6* gene is found here. The 5' nuclease assay was validated on previous test material including 16 wildtype homozygote samples, 16 heterozygotes, and 16 homozygotes for the \*2 allele (Table 2). Two samples previously tested as heterozygotes were in the new assay tested as homozygote carriers of 2850T. This is in concordance with the original result with the genotype \*2/\*41, as both alleles \*2 and \*41 contain this polymorphism (Table 1).

The exon 5 of *CYP2D6*, where the allele \*3 deletion 2549delA resides, is highly homolog to the sequence of its pseudogene *CYP2D7*.<sup>44</sup> Because of this, locations for placing specific primers are significantly restricted. The forward primer for the 5' nuclease *CYP2D6*\*3 assay is located 67 bp upstream of the probe, providing specificity to the *CYP2D6* gene sequence by a T>C difference to *CYP2D7* within the last five bases of the 3' end (Table 3). The reverse primer is located outside of exon 5, covering a sequence where *CYP2D7* and *CYP2D8* have a “-CT-” insert not present in the wildtype *CYP2D6* gene. Together, the primers generate a 341 bp amplicon.

Although allele \*3 is one of the most frequently found nonfunctional alleles of the *CYP2D6* gene, homozygote carriers are rare.<sup>37,46</sup> Only a single sample containing \*3 in combination with a deleted *CYP2D6* gene (allele \*5) was therefore available for the validation of the 5' nuclease assay (Table 2). The \*3/\*5 genotype results in a similar signal as a homozygote \*3/\*3 in the allele discrimination plot. For validating the 5' nuclease assay, the single sample was therefore used as a homozygote mutant, together with 24 wildtype homozygotes and 23 heterozygotes for \*3 allele. Of the total 48 samples used for validating the *CYP2D6*\*3 assay, three failed to amplify, while the result of the remaining 45 conformed to the original test results (Table 2).

The 1846A SNP used for identifying the *CYP2D6* allele \*4 is located in exon 4 of the gene.<sup>44</sup> The region has a high

**Notes:** Specificity of sequences and optimized concentrations of primers and probes for each of the II assays presented in this paper. Wildtype probes were labeled 5' with FAM and 3' with BHQ-I, while mutant probes were labeled 5' with CalFluor 540 (a TET analog), and 3' with BHQ-I. The probes used for *CYP2C19*\*4 were synthesized using phosphorothioate bases (u, c). Amplicon size generated by the primers is shown on the right. Sequence color codes: light gray – *CYP2D6* nucleotides deviating from *CYP2D8*; medium gray – *CYP2D6* nucleotides deviating from *CYP2D7*; reverse black – bases deviating from both *CYP2D7* and *CYP2D8*, including inserted bases (*CYP2C9* for the *CYP2C19* assays). Underlined bold indicates target SNPs/mutations in either the wildtype or the mutant probe. – indicates one-base insert present in pseudogene or mutant target.

**Abbreviations:** FAM, carboxyfluorescein; BHQ-I; black hole quencher-I; TET, tetrachlorofluorescein; SNP, single-nucleotide polymorphism.

homology to the gene sequence of *CYP2D7* and to a less extent to *CYP2D8*. Because of this, and to minimize the amplicon length, the specificity of the 5' nuclease to the *CYP2D6* gene sequence is achieved solely based on a three-

base heterology between the forward primer and the homolog sequence of the *CYP2D7* pseudogene (Table 3). Two of these bases are located in the immediate 3' end of the primer, ensuring the specific amplification of the 154 bp product.

The 5' nuclease assay for *CYP2D6* allele \*4 was validated on 16 samples homozygote for the 1846G (wildtype), 16 heterozygotes, and 16 samples homozygote for the mutant 1846A. All test results conformed to those of the original reports, and no samples failed to amplify in this assay (Table 2).

The immediate area (~100 bp upstream and ~40 bp downstream) surrounding the *CYP2D6* allele \*6 founder mutation 1707delT in exon 3 is highly conserved between the *CYP2D6* and *CYP2D7* gene.<sup>44</sup> For this reason, the forward primer of the 5' nuclease assay is located 131 bp upstream from the probe site, while the reverse primer is located 25 bases downstream. The latter primer covers the same sequence as that used for the forward primer of the allele *CYP2D6*\*4 assay and also includes the \*8 1758G>T in the 5' end of its sequence.<sup>27</sup> Similarly, the probe sequence of the assay includes the 1716G>A of alleles \*45 and \*46.<sup>27</sup> The product generated using the two primers is 212 bp long (Table 3).

Although, allele \*6 is found at a frequency of ~0.6 in Caucasians, homozygote carriers are rare.<sup>25,37,47</sup> The only such sample available for validation of the 5' nuclease assay was a \*5/\*6x2. This sample generates a signal that is similar to that of a \*6/\*6 genotype. When validating the assay, the \*5/\*6x2 sample was included in replicates together with 22 heterozygote samples and 24 previously tested as homozygote of the wildtype sequence. All results of the 5' nuclease assay were consistent with that of the original tests (Table 2).

Due to the high homology between the sequence of *CYP2D6* and that of *CYP2D7*, the 5' nuclease assay for alleles \*3 and \*9 shares the same set of PCR primers (Table 3).<sup>44</sup> For the verification of the 5' nuclease assay of allele \*9, five archival samples previously tested as either \*5/\*9 or \*9/\*9 were available. These samples were used (one in replicate), together with 26 heterozygotes and 16 wildtype homozygotes. Of the five homozygote samples, two failed to amplify. The results of all the remaining samples, including both heterozygotes and wildtype homozygotes, were consistent with that of the original test (Table 2).

The 100C>T used to identify *CYP2D6*\*10 is located in exon 1 of the gene. This region also has a high sequence homology to that of *CYP2D7* but low compared to *CYP2D8*.<sup>44</sup> Several other mutations defining alleles of the *CYP2D6* gene have been identified in this exon. These include the 31G>A of \*35, 77G>A of alleles \*43 and \*46, the 124G>A of allele \*12, and the T insertion at 137–138 found in allele \*15.<sup>27</sup> To avoid coamplification of *CYP2D7*, the forward primer of the 5' nuclease assay is located, so it has three bases heterolog

to this gene sequence, two of which are located at the 3' end of the primer (Table 3). The reverse primer is located 134 bases downstream. It further increases the specificity for the *CYP2D6* gene, by spanning a sequence containing a "T" insert in the *CYP2D7* gene. In addition, the probe sequence also contains two-nucleotide differences to the sequence of this pseudogene (Table 3).

For validation of the *CYP2D6*\*10 assay, 61 archival samples were retested. These consisted of 20 samples homozygote for the 100C, 21 heterozygotes, and additional 20 samples homozygote for the variant 100T. In the latter two groups, samples containing allele \*4 were included to increase the total number of tests harboring this SNP.<sup>27</sup> One sample originally genotyped as \*2/\*10 gave a wildtype signal for the 100C>T in the 5' nuclease assay, while a second came out as heterozygote compared to the initial result that was as a homozygote wildtype (\*1/\*2). In both cases, the accuracy of the 5' nuclease assay was confirmed by direct sequencing of the PCR product (data not shown).

The sequence of exon 2 harboring the *CYP2D6*\*17 1023C>T is somewhat less conserved between *CYP2D6* and *CYP2D7*. This, like in the case of allele \*2, makes it easier to design a specific set of primers for the assay. The region contains a high number of other SNPs, including the 974C>A found in some forms of allele \*4.<sup>27</sup> The primers designed for the *CYP2D6* allele \*17 5' nuclease assay amplify a 127 bp fragment (Table 3). The forward primer is located 27 bases upstream from the probe and covers the location of the 974C>A transversion. The reverse primer resides 43 bases downstream from the probe. Although the forward primer has a two- to three-base difference to that of the sequence of the two pseudogenes, most of the specificity is achieved by the reverse primer. This primer has a deletion of a C that is present in the sequence of *CYP2D7* and *CYP2D8*, together with three additional heterolog base positions.

As the *CYP2D6* allele \*17 is rare in Caucasians, only two heterozygote samples and no homozygote mutants were available for the validation of the 5' nuclease assay.<sup>37,47</sup> Because of this, eight replicates of each of the two heterozygotes, together with 32 wildtype homozygote samples for the 1023C>T SNP, were used (Table 2). All retest results performed using the 5' nuclease assay correlated with that of the previous findings.

The recently discovered 2988G>A SNP of allele \*41 is located in the intron, 38 nucleotides upstream from exon 6.<sup>42,44</sup> This region has a relatively high degree of sequence heterology between the *CYP2D6* and the two pseudogenes,

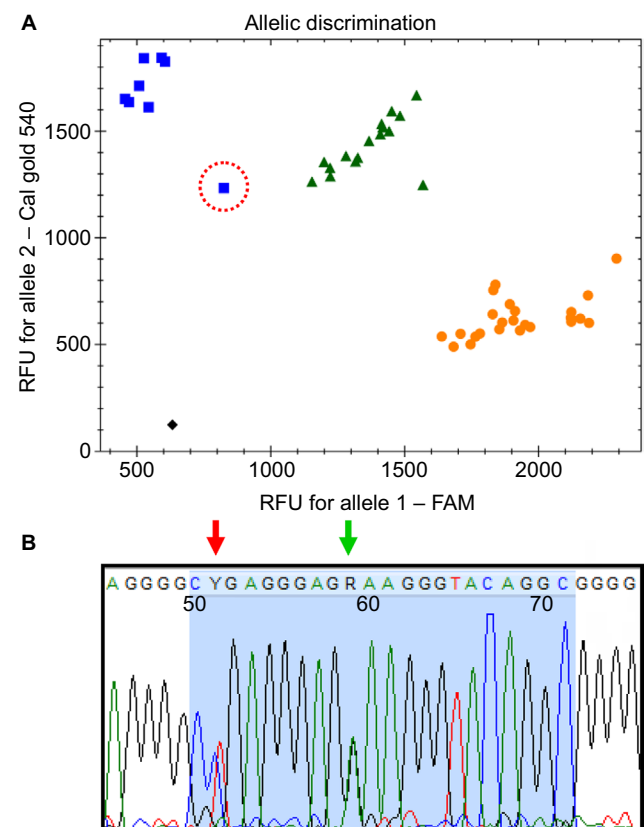

making it a more ideal target for designing a 5' nuclease assay. As such, the forward and reverse primer is located in close proximity to the probe, generating an amplicon only 77 bp long (Table 3). Validation of the assay was performed using archival material consisting of 16 homozygote \*1/\*1 samples, 16 samples previously genotyped as heterozygote carriers of the \*41 allele, and 16 samples tested as homozygotes. The \*1/\*1 samples were selected since these neither contain the -1584C>G nor the 2850C>T SNP.<sup>27</sup> As such, the 5' nuclease assay was expected to correlate with the original test result, although the RFLP assay did not target the same SNP as the 5' nuclease assay does. Genotyping of the samples confirmed this prediction, while three samples of the heterozygote and seven of the homozygote for the 2988G>A SNP did not agree with the original test result of the RFLP (Table 2). The ten samples that differed were further validated by parallel testing at Diakonhjemmet Sykehus, Oslo, Norway, using a commercial TaqMan assay (Thermo Fischer Scientific). This test confirmed the results of the 5' nuclease assay for all but one. The single sample that did not comply was originally genotyped as \*1/\*41, while it was typed as a \*41/\*41 homozygote by the 5' nuclease assay (Figure 1A). In the allele-discriminating plot of the real-time assay, its signal was located between the other homozygote \*41/\*41 samples and those of the heterozygotes (Figure 1A). The heterozygosity for the 2988G>A was established by direct sequencing of the PCR product (Figure 1B). However, this method also identified a second SNP. This second SNP at 2980 nt is a heterozygote C>T transition in the sample, positioned at the second base in the probe sequence.

To estimate the numbers of patients incorrectly genotyped with the \*41 based on the RFLP assay, all available archival samples containing this allele were retested using the 5' nuclease assay (Table 4). The result of the 5' nuclease assay was in agreement with the original test results for 78 of these. As both 2850T and -1584C are also present in allele \*4K,<sup>47</sup> the remaining 19 unresolved samples that did not comply and which originally had been genotyped as \*5/\*41, \*41/\*41, 2x\*41/\*41, or \*17/\*41 were also tested using the *CYP2D6*\*4 assay. This was done since the original RFLP setup for genotyping *CYP2D6* branched off based on the result of the 2850C>T assay, and therefore, the allele \*4K would have been wrongly identified as allele \*41.<sup>36</sup> Retesting these homozygotes of 2850C>T led to identification of four samples as heterozygote carriers of the 1846G>A SNP and hereby of the *CYP2D6*\*4K allele.

## Optimization of PCR setup for routine testing

The *CYP2C19* and *CYP2D6* test panels have been set up for routine testing in our laboratory. The *CYP2D6* panel is used together with the copy number variation test previously published by Schaeffeler et al.<sup>41</sup> This test provides identification of the \*5 deletion together with copy number variations of the gene. The panels are optimized for a 96-well PCR-plate setup, where each of the *CYP2C19/CYP2D6* assays is tested in a dedicated row. Using a primer/probe multimix and reaction mix, a master mix for each assay is prepared in the last cell in the row using 10 µL per reactions. This master mix is then distributed into each well in the same row. The setup includes three controls. A universal \*1/\*1 wildtype used for all assays (W), a homozygote mutant (M when available, else a heterozygote T), and a no template control. Their locations are fixed in the first three columns. Using repeated dispensing, 2 µL template DNA (~30–100 ng total) is added as a drop

**Figure 1** (A) Allelic discrimination plot of the *CYP2D6*\*41 assay, showing the 48 samples used for validating the test; X-axis: FAM fluorescence – wildtype probe; Y-axis: CalFluor gold 540 – mutant probe. Ambiguous sample is marked with a red circle, while black square represents “no template” control (NTC). (B) Sequence of the probe region (blue area) of the ambiguous sample. Green arrow marks the 2988G>A SNP, while the red arrow shows the location of the 2980C>T SNP. **Abbreviations:** FAM, carboxyfluorescein; SNP, single-nucleotide polymorphism.

**Table 4** Retest of *CYP2D6*\*41 alleles based on the presence of the 2988G>A SNP

Original genotyping result	Total *41 alleles retested/no. of samples	Failed no. of alleles in retest	Frequency of failed retest
*1/*41	4	1	0.25
*2/*41	34	0	0.00
*4/*41	35	7	0.20
*5/*41	6	1	0.17
*6/*41	1	0	0.00
*17/*41	1	1	1.00
*41/*41	24	11	0.42
2×*41/*1	2	0	0.00
2×*41/*41	9/3	7	0.78

**Notes:** Retesting of samples originally tested as either heterozygote or homozygote carriers of *CYP2D6* allele \*41, based on the presence of the 2850C>T and lack of the –1584C>G SNP. Failed number of alleles are alleles not found to harbor the 2988G>A SNP in the retest. For samples with copy variations, the number of alleles has been set as either 2 (2×\*41/\*1) or 3 (2×\*41/\*41).

**Abbreviation:** SNP, single-nucleotide polymorphism.

onto the sides of each well hereby minimizing the change of tips. The plates are then sealed and briefly centrifuged to mix DNA and mastermix. The whole procedure takes less than 1 hour for a full 96-well plate.

## Discussion

Although there is strong scientific evidence linking the genotype of *CYP2D6* and *CYP2C19* to the metabolic status of their substrate drugs, the clinical application and routine use of these tests are still under debate. The ongoing discussion has been further intensified by the social–economic aspect of having expensive molecular assays, which do not give an unequivocal clinical answer.<sup>4</sup> New genotyping tests should therefore preferably increase the precision by including the clinically most relevant alleles of each gene, while lowering the total cost by reducing price of reagents as well as labor.<sup>4,48</sup>

Following the decision to modernize the genotyping assays at the laboratory of the Danish Epilepsy Centre, several alternative techniques were evaluated before selecting the 5′ nuclease real-time PCR as the platform. Decisions were based upon the speed of setting up assays, total cost of reagents, hands-on time during routine testing, as well as number of recognizable alleles. Several commercial available platforms exist that are capable of discriminating between a high number of *CYP2D6* alleles using DNA chip (GenoChip *CYP2D6*, <http://www.pharmgenomics.de>; AmpliChip Cyp450 kit, <https://molecular.roche.com>) or bead chip (Luminex, <http://www.luminexcorp.com>) technology.<sup>32,33,49</sup> These together with HRM and the commercial TaqMan assays (Life Technologies) were considered before the decision was made to design the two test panels presented in this study. Table 1 shows a comparison between the 5′ nuclease panel for *CYP2D6*, the Luminex XTag *CYP2D6* v.3 kit, and the Roche AmpliChip P450 kit.<sup>32,49</sup> The two commercial kits are capable of recognizing 16 and 24 different signature SNPs/

mutations of *CYP2D6* (excluding duplications), compared to the eight identified by the 5′ nuclease assays. However, of the additional 16 alleles that the AmpliChip P450 kit can identify, allele \*35 encodes normal enzyme activity, while the activity of \*25, \*26, and \*30 is not known (Table 1). Also, of the nonfunctional alleles identified by this method, \*8, \*11, \*14, \*19, \*31, and \*40 are extremely rare in Caucasians (Table 1),<sup>37,46,47,50</sup> while the remaining alleles \*7, \*15, \*20, \*29, and \*36 have reported frequencies between 0.0 and 0.6, which are also too low to be categorized as polymorphisms according to Cavalli-Sforza and Bodmer.<sup>51</sup> Therefore, although both the AmpliChip P450 and the Luminex XTag *CYP2D6* kit unarguably deliver a better prediction of the actual genotype by their higher number of detectable SNPs/mutations, the difference is only marginal, if measurable, when predicting the clinically relevant phenotypic level.<sup>52</sup>

The main advantages of the direct approach for genotyping *CYP2D6* are less hands-on time during setup, and that the PCR is performed in a closed system, hereby minimizing the risk of contamination. In contrast, the drawback is the restriction put on the design of the PCR primers, due to homology between the target and pseudogene.<sup>44</sup> As a second direct genotyping method, HRM was considered, since several assays for genotyping *CYP2D6* and *CYP2C19* using this approach have already been published.<sup>38,39,53</sup> This method has the benefit of reducing cost and maintenance of assays, since it does not rely on the use of specific fluorescence-labeled oligoprobes.<sup>38</sup> While validating the primers designed for the two 5′ nuclease test panels, their suitability for use in HRM assays was also evaluated (data not shown). Most of the primer sets generated robust and consistent amplicons, facilitating genotyping using this method. However, the high degree of polymorphism in *CYP2D6*, and the tendency of these to cluster around certain regions of the gene, makes the method less suited for routine testing. A good example

of this is the primer used for identifying *CYP2D6* allele \*6, which spans a 212 bp region at exon 3.<sup>44</sup> This region also includes the common 1661G>C SNP as well as a number of more rare polymorphisms (e.g., 1704C>G, 1724C>T, 1757C>T, 1758G>A).<sup>27</sup> These additional SNPs generate alternating melting curves, which would have to be characterized, and demand additional PCR controls, before robust genotype results can be obtained.<sup>53</sup> The only way of reducing these alternating forms would be to minimize the size of the amplicon, centering it in on the 1707delT. This, however, is not possible due to the high homology in this region between *CYP2D6* and *CYP2D7*. Therefore, HRM in our opinion would not in its current stage of development be the method of choice for routine testing of *CYP2D6*. However, for less polymorph genes, the technique may still be applied. One example where it can prove useful is for the detection of *CYP2C19* allele \*17. The C>T transition of this allele has an immediate area containing a high number of adenine and thymine bases (data not shown), which would result in a very long probe for the 5' nuclease assay in order to obtain an optimal annealing temperature. During the current study, we tried without any success to design a 5' nuclease assay capable of selecting against this SNP and are now pursuing the use of HRM instead.

During their time of storage, some of the reference samples were used as controls for the genotyping tests in the laboratory. In this process, they underwent cycles of repeated thawing and freezing that causes both degradation and fragmentation of DNA. For the validation of the assays, however, samples were not selected based on their DNA concentration nor was this normalized between them. Given that a variation in amplification efficiency hereby is expected, the overall success rate of both amplification and correct calls of genotype might be taken as an indicator of the robustness of the assays. Of the 381 samples used for validating the eight *CYP2D6* assays, only five failed to amplify during the initial PCR (Table 2). These were all samples used for validating the *CYP2D6*\*3 and \*9 assays. Due to a particular high homology in this region between the gene sequences of *CYP2D6* and *2D7*, these two tests share a common set of primers that amplify a 341 bp fragment ([Supplementary materials](#)). This is a length commonly regarded as suboptimal for 5' nuclease assays due to both an increased chance of abolishment of elongation by the polymerase and a higher chance of breaks in the DNA template to occur as the length increases. Efforts to optimize the two assays, by reducing the size of the amplified fragment, did not increase the strength of the signal (data not shown). Therefore, although the primed

region is not an ideal length for 5' nuclease genotyping, the proposed design for the two assays seems most optimal in order to avoid a nested PCR.

During the validation of the 11 5' nuclease assays, only three out of 541 results did not comply with that of the original test. Two of these were samples that were used for validating the *CYP2D6*\*10 assay (Table 2). In both cases, the result of the 5' nuclease test was confirmed by sequencing the PCR product. In the case of the third sample, this was originally identified as a \*1/\*41 heterozygote using RFLP, while it was genotyped as a homozygote carrier of the 2988G>A SNP by the 5' nuclease. Subsequent parallel testing at a second laboratory applying the commercial TaqMan test confirmed the original result of the RFLP assay. The allele-discriminating plot for this sample showed a decreased signal compared to both other homozygotes of the 2988G>A (CalFlour540 signal) and heterozygote samples (FAM signal) (Figure 1A). Sequencing of the amplicon identified a second SNP 2980C>T, located at the 5' end of the probe. Given that the FAM signal is decreased for this sample (Figure 1B), this indicates that the SNP must interfere with the binding of the wildtype probe on the \*1 allele in the sample. Since TaqMan MGB probes bind with higher affinity to their target, they are generally shorter than regular 5' nuclease probes. This is the most likely reason why the parallel test performed at Diakonhjemmet Sykehus had an increased signal for the wildtype allele of this sample, compared to the 5' nuclease assay, hereby assigning the correct genotype. To further investigate the occurrence of this novel SNP, a Blast search was performed using the 2980T sequence (<https://blast.ncbi.nlm.nih.gov/Blast.cgi>). This search did not return any direct hits in the GenBank nonredundant database. Also, this SNP is not included in any currently described alleles listed in the Human Cytochrome P450 allele database.<sup>27</sup>

In the first characterization of the *CYP2D6* allele \*41, this variant was recognized based on the presence of the 2850C>T SNP, and the lack of -1584C>G, distinguishing it from allele \*2A.<sup>54,55</sup> Later studies by Raimundo et al<sup>42</sup> and Toscano et al<sup>43</sup> have proven that the aberrant splicing of this variant is due to a single G>A transition located at 2988 nt in the gene. The paradigm shift leading to the changed definition of *CYP2D6* allele \*41 causes previous test results lacking the 2988A but containing the 2850T and -1584G to be reclassified as *CYP2D6*\*2B-M.<sup>27,42,43</sup> Therefore, in order to verify the results of the original RFLP assay, all achieved samples previously tested as homozygote or heterozygote carriers of the \*41 allele were retested for the presence of the 2988G>A SNP. Of the 97 samples, 39 had in the original result been

phenotyped as extensive metabolizers (EMs) having a normal functioning allele (\*1 or \*2) together with allele \*41 (Table 4). The remaining 58 samples were IMs, with the RFLP test showing either a homozygote carrier of allele \*41 or in combination with a decreased/nonfunctional allele (\*3, \*4, \*5, \*6, or \*17). Of the EM group, only one sample did not confer to the original test result, hereby having a failed retest frequency per allele of 1.3% (1/76 alleles). The same calculated frequency for IM heterozygotes of allele \*41 was 20.9% (9/43 alleles) and for homozygotes 41.6% (10/24). In 17 cases, retesting for the 2988G>A led to a change in phenotype from IM to EM. In one case, a sample previously tested as a 2×\*41/\*41 duplicate was by the 5′ nuclease assay genotyped as a 2×\*2/\*2, resulting in a change of phenotype from IM to ultrafast metabolizer. Given that the AmpliChip Cyp450 test was designed before the assignment of 2988G>A as the founder SNP of allele \*41, a similar error rate when predicting the phenotype result is expected for patients genotyped using this system.<sup>33</sup>

The original RFLP *CYP2D6* test used at the Danish Epilepsy Centre divided the alleles into two groups based on the presence of the 2850C>T SNP.<sup>36,37</sup> Using this approach, any sample identified as either of the two types of homozygotes in the assay would subsequently only be tested in one of two subcategories. The group consisting of carriers of 2850C would be assayed for the alleles \*3, \*4, \*6, \*9, \*10, and \*13/\*16, while the second group homozygote with the mutant 2850T would only be tested for the presence of alleles \*2, \*8, \*11, \*12, \*17, and \*41.<sup>24,37</sup> While this setup was designed to facilitate fast clinical results reducing labor and overall cost of a test, one *CYP2D6* subtype does not comply with this design. The allele \*4K is characterized by harboring the 1846A founder SNP of *CYP2D6* allele \*4 as well as the 2850T used for deselecting samples from being tested in the *CYP2D6*\*4 assay.<sup>47</sup> The *CYP2D6*\*4K was originally described by Sachse et al<sup>47</sup> denoted as allele \*4E in the paper; however, to our knowledge, the frequency of this particular allele is not known. As part of the retesting of *CYP2D6*\*41, all original tests reported as \*41/\*41 homozygotes, which could not be confirmed as carriers of the 2988G>A SNP, were also retested using the *CYP2D6* allele \*4 assay. This identified four samples as \*4K, leading to an estimated frequency of 0.4% in 1046 submitted samples. In all four samples, this caused a change of phenotype from IM to EM, as neither of these contained the 2988G>A transition.

Following validation of the *CYP2D6*\*17 assay and setup of the test panel in the routine laboratory, a decreased signal

for this assay was observed for samples tested as homozygotes for the \*4 allele. Investigations showed this to be caused by the presence of the 974A on both alleles, which destabilizes the forward primer leading to reduced signal.<sup>27</sup> For one rare sample identified as \*4/\*17, this caused a contradictory result as a homozygote (although with decreased signal) of the 1023C>T SNP, while correctly being genotyped as heterozygote for the 1846G>A. A similar ambiguous result was recently reported for the commercial TaqMan *CYP2D6* assay (Life Technologies), although here, the mechanism behind could not be elucidated.<sup>56</sup> Together with the report on ambiguous samples of *CYP2D6*\*41 when comparing the Genochip and AmpliChip (in addition to other reports of failed test using commercial platforms), this highlights the complexities involved in genotyping the *CYP2D6* gene and the need for expert knowledge on the performance of the assay in use.<sup>33,48,57,58</sup> In our experience, this is best obtained using an open-source system, as it allows ambiguous or “no call” results to be resolved based on known primer and/or probe sequences. In the case of the *CYP2D6*\*17 forward primer, its performance on a \*4 background may be increased by using a degenerate base or including inosine at this position in the primer.

In conclusion, we have designed and thoroughly validated two test panels for genotyping *CYP2D6* and *CYP2C19*. The panels have been optimized for routine use in the laboratory, providing a cost- and time-efficient method that we believe is comparable or superior to most commercial kits.

## Acknowledgments

The authors thank method specialist Linda Hårstad Uthus from Centre of Psychopharmacology, Diakonhjemmet Sykehus, Oslo, Norway, for providing additional sample material and performing parallel testing. They would also like to thank Peter Bøhm and Lars Ødum MD at Zealand University Hospital, Roskilde for helping out with sequencing of samples. In addition, they are indebted to Dr. James Kennedy from the Icelandic Marine Research Institute, who helped during the preparation of this manuscript.

## Disclosure

The authors report no conflicts of interest in this work.

## Pharmacogenomics and Personalized Medicine

### Publish your work in this journal

Pharmacogenomics and Personalized Medicine is an international, peer-reviewed, open access journal characterizing the influence of genotype on pharmacology leading to the development of personalized treatment programs and individualized drug selection for improved safety, efficacy and sustainability. This journal is indexed on the American Chemical

Society's Chemical Abstracts Service (CAS). The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/pharmacogenomics-and-personalized-medicine-journal>
