Abstract: In both developed and developing countries, pediatric obesity and type 2 diabetes are an increasing public health concern: globally 5.6% of girls and 7.8% of boys aged ≥ 5 years have obesity. The incidence of type 2 diabetes has increased in youth in recent decades and disproportionately affects those from ethnic/racial minority groups and disadvantaged backgrounds. For the treatment of both conditions, conventional lifestyle intervention is frequently ineffective, access to bariatric surgery is very limited and many young people are unsuitable or unwilling to undergo surgery. A very-low-energy diet (VLED) provides a viable alternative and may be effective for weight reduction and improved glycemic control in youth, based on one systematic review. In particular, in the treatment of type 2 diabetes, a chart review and a pilot study both demonstrated that a VLED can reduce the requirement for medications, including insulin, and lead to the remission of diabetes. However, long-term follow-up and safety data remain limited and therefore a VLED is inconsistently recommended by clinical practice guidelines for the treatment of pediatric obesity and type 2 diabetes. In clinical practice, VLED use in children and adolescents is uniquely challenging due to intolerance of expected side effects, difficulty adhering to the highly restrictive diet and difficulty with behaviour change within the current social context and environment. Ultimately, more research, including larger, longer-term trials with comprehensive safety monitoring are required to strengthen the evidence base. This would inform clinical practice guidelines, which may facilitate more widespread utilization of VLED programs in the management of obesity and type 2 diabetes in youth.

Introduction

In both developed and developing countries, pediatric obesity and type 2 diabetes are an increasing public health concern: globally 5.6% of girls and 7.8% of boys aged ≥ 5 years have obesity.¹ The worldwide incidence of child and adolescent obesity is increasing with an estimated 158 million affected in 2020 and 254 million by 2030.² Population-based epidemiological data for type 2 diabetes in children and adolescents are limited, but largely indicate increasing incidence rates in developed countries in recent decades.^{3,4} In the SEARCH for diabetes in youth study, the US type 2 diabetes incidence increased from 9.0 per 100,000 in 2002–2003 to 13.8 in 2014–2015 in youth aged 10–19 years, which equates to an annual percentage change of 4.8%.⁵ Incidence of type 2 diabetes is disproportionately higher in youth from certain at-risk groups, including ethnic/racial

minorities and those from disadvantaged backgrounds.^{6–9} Increasing rates of type 2 diabetes in young people is especially concerning given the earlier onset of related complications and mortality in those with younger compared with older onset of type 2 diabetes.^{9,10} The increasing prevalence of obesity and type 2 diabetes and the poor prognosis of type 2 diabetes in young people pose significant clinical challenges that require effective treatment strategies.

Clinical practice guidelines describe weight loss as a primary goal in the treatment of pediatric obesity in the presence of comorbidities, severe obesity and type 2 diabetes.^{11,12} It is recommended that weight loss be achieved using a lifestyle modification program that incorporates nutrition and physical activity education, encouraging sustained behavior change.^{11,13} In type 2 diabetes, once metabolic stability is achieved, lifestyle intervention with metformin therapy is recommended as first-line treatment.^{12,14,15} Systematic reviews of pediatric obesity treatment demonstrate that conventional lifestyle modification programs lead to modest weight loss in the short-to-medium term.^{16–18} However, many youth with obesity do not respond to conventional treatment,^{19,20} and, similarly, many youth with type 2 diabetes do not respond to traditional diabetes therapy. In the TODAY study, the largest clinical trial conducted to date comparing type 2 diabetes treatment options for 699 10–17 year olds in the US, lifestyle modification with metformin led to meaningful weight loss for only one-third of adolescent participants.²¹ Additionally, one half of participants experienced glycemic control failure after 12-months of treatment. Hence, alternate interventions are required for those who do not respond to conventional therapy.

Bariatric surgery is an effective alternate treatment for both pediatric obesity and type 2 diabetes.^{9,22,23} However, surgery will not be suitable for many young people who may not have the maturity or required family support to comply with the necessary postoperative behaviors.^{24,25} Access to surgery varies worldwide but is limited and expensive.²⁶ An intermediate step is needed to bridge the treatment option gap between a conventional lifestyle modification program and bariatric surgery. The emerging evidence base for novel dietary approaches in adults has led to investigation of more intensive dietary therapies for pediatric obesity and type 2 diabetes. One such approach is a very-low-energy diet (VLED). However, there has been little commentary on their role in the treatment of obesity and type 2 diabetes in young people. Hence, the aim of this review is to provide an overview of the current perspectives and literature in this space.

What is a VLED?

There is no standard definition for a VLED, however, it typically involves an energy intake prescription of ≤ 800 kcal per day for the purpose of achieving rapid weight loss.^{27,28} A VLED is usually low in carbohydrate (eg, <50 g/day) and high in quality protein (minimum of 0.8–1.5 g/kg body weight per day) in order to preserve lean body mass.²⁹ Due to the low carbohydrate content, VLEDs can induce a mild state of ketosis as evidenced by an increase in circulating blood ketone concentration.³⁰ This process can aid lean mass preservation and facilitate appetite suppression.^{30,31} A high calorie-free fluid intake (eg, 2 L per day) is also recommended. Typically, a VLED is prescribed as a short-term approach (eg, 8–12 weeks), under the guidance of a trained health professional.

VLEDs can be administered as either a meal replacement or food-based diet. Meal replacements are more commonly used whereby the individual replaces some or all foods with commercially formulated products eg, shakes, soups, bars or desserts.^{29,31} Many commercially available products exist and there is wide variability between products in terms of nutritional content, nutritional adequacy and cost.³² Several are nutritionally complete in line with adult requirements due to supplementation with essential vitamins and minerals, giving rise to their popularity.³³ However, a multivitamin may be required to meet nutritional adequacy in children and adolescents due to increased micronutrient requirements associated with growth.

A food-based VLED is more commonly termed a “protein sparing-modified fast” in the literature. Compared to the advised minimum protein intake of 0.8–1.5 g/kg body weight per day for a VLED, more protein is prescribed when using a food-based VLED with pediatric obesity treatment studies reporting protein prescription typically in the range of 1.5–2 g/kg body weight/day, but as high as 3 g/kg body weight/day.²⁷ Vitamin and mineral supplementation eg, potassium chloride, calcium carbonate, vitamin K, magnesium, and sodium, are also typically used in conjunction with the diet to enhance nutritional adequacy.²⁷

Systematic Review of VLED in Pediatrics

One systematic review in 2019 evaluated the use of VLEDs in young people with obesity and type 2 diabetes.²⁷ This review identified 24 studies that used a VLED program (≤ 800 kcal/day) for weight management in a total of 674 children and adolescents, aged five to 18 years. All study

designs were included to allow for evaluation of the safety of VLEDs in this population and have been summarized in Table 1. Meta-analysis of 20/24 included studies indicated that a VLED program of 3 to 20 weeks duration resulted in a significant mean (SD) weight loss of 10.1 (0.7) kg suggesting the overall short-term effectiveness of a VLED program for weight loss (Figure 1A). At latest follow-up (20 weeks to 14.5 months from baseline), weight loss was 5.3 (1.4) kg in seven studies (Figure 1B). This is more weight loss compared with the weight loss reported at latest follow-up in the 2017 Cochrane reviews of the impact of conventional pediatric multidisciplinary weight management interventions.^{17,18} In these reviews mean weight change was -1.45 kg (95% CI, -1.88 to -1.02, $P < 0.001$) for children¹⁸ and -3.67 kg (95% CI, -5.21 to -2.13, $P < 0.001$) for adolescents.¹⁷ However, the Cochrane reviews included studies that recruited children and adolescents with both overweight and obesity, compared with obesity only in the VLED review. Additionally, the Cochrane reviews included a follow-up period ranging from 6-months up to 3-years, compared with 20-weeks to 14.5-months in the VLED review. Despite these differences, the overall findings from the 2019 systematic review

highlight that a VLED program is an effective intervention for weight loss and may be a feasible alternate treatment option for young people (Table 2).

VLED for Obesity

Of the 24 published studies identified by the 2019 systematic review, 22 utilized a VLED program to treat pediatric obesity specifically.²⁷ Only two of these studies were published after 2000 highlighting a lack of recent data in this area. To the best of our knowledge, there have been no relevant trials published since the 2019 systematic review.

VLED for Type 2 Diabetes

The 2019 systematic review identified two published studies that implemented a VLED in young people with type 2 diabetes. One was a chart review³⁴ and the other a pilot intervention study in eight participants.³⁵ Both studies demonstrated significant weight loss and improvements in multiple aspects of diabetes, including improved glycemic control and reduced medication use. In particular, both studies reported that all except one participant receiving insulin therapy at

commencement of the VLED program ceased insulin and remained insulin-free for the duration of the chart review period/trial.³⁵ Improvements in glycemia were also significant, including reduction in glycated hemoglobin (HbA1c) from 8.8% (SD 0.6) to 7.4% (0.6) in the chart review³⁴ and normalisation of fasting glucose, 2-hour glucose and HbA1c in four of five study completers in the pilot study.³⁵ The one completing participant in the pilot study that did not have remission of their diabetes (defined¹⁴ as HbA1c <6.5%, (<48 mmol/mol), fasting plasma glucose <7.0 mmol/l and 2 h post-glucose load plasma glucose <11.1 mmol/l) had type 2 diabetes for the longest duration (3.25 years). The authors of the pilot study suggested that implementation of a VLED program early

following diagnosis of type 2 diabetes may be an important consideration when aiming for diabetes remission, recommending a window of within 6-months from diagnosis.³⁵

While limited, the data from these two small studies suggest that VLED programs may be particularly useful for the treatment of type 2 diabetes in youth. However, there is no long-term data in this area, and little is known about whether remission of diabetes is maintained beyond 6-months post intervention. It is likely that some form of continued intervention following the initial VLED program will be required to maintain benefits attained, including interventions focused on sustained nutrition and physical activity behavior change.

VLEDs in Adults

The adult literature on the use of VLEDs in the treatment of obesity and type 2 diabetes is more extensive. The long-term effectiveness of a VLED for weight loss compared with conventional approaches was reported in a 2016 systematic review of the literature which reported that a VLED program resulted in 3.9 kg more weight loss at 1 year, 1.4 kg more weight loss at 2 years, and 1.3 kg more weight loss at 3 to 5 years.³⁶ Additional benefits have been described including a 2019 systematic review, which reported that subjective depressive symptoms improved following a VLED program that was at least 8 weeks long and included behavioral therapy and low intensity exercise.³⁷ Furthermore, a systematic review of three trials evaluating the experiences of people using a VLED program for weight loss found that a VLED program was well accepted and positively viewed by participants.³⁸

The Diabetes Remission Clinical Trial (DiRECT) in the UK is a landmark study investigating the effectiveness of a VLED program to treat type 2 diabetes in adults that has received considerable media attention worldwide. Following on from several smaller studies,^{39–41} the DiRECT trial demonstrated remission of type 2 diabetes (defined as HbA1c less than 6.5% (48 mmol/mol)) in almost half of the participants following a VLED in a primary care setting, with remission sustained up to 24-months from baseline.^{42,43} The DiRECT study has also published cost-effectiveness data demonstrating that, compared to standard care, a VLED intervention to treat type 2 diabetes is more cost effective, due to related cost savings from achieving diabetes remission, even if only temporary.⁴⁴ Such cost saving benefits may be greater in the adolescent population for whom the progression of diabetes is more rapid with earlier onset of complications.

The DiRECT study has also published work describing the proposed mechanism for type 2 diabetes remission related to weight loss achieved during a VLED.⁴⁵ They demonstrate that individuals who adhere to the VLED and achieve rapid weight loss have reductions in triglyceride production by the liver and reduced pancreatic fat that leads to improved beta-cell function and remission of diabetes.⁴⁵ If weight loss is maintained, levels of triglyceride production and pancreatic fat stabilize at these lower levels, and diabetes remission is sustained during the 2-year follow-up period. Re-emergence of type 2 diabetes was associated with weight re-gain, increased production of triglyceride by the liver, increased pancreatic fat and deterioration of beta-cell function. The importance of weight loss for diabetes remission was highlighted by a 2020 study demonstrating that a VLED program is as successful at achieving type 2 diabetes remission as bariatric surgery when similar weight loss is achieved.⁴⁶ Similarly, a 2020 systematic review of 18 studies reported that, compared to bariatric surgery, VLEDs offered comparable effects on weight loss, glycemic control, triglycerides, and insulin resistance and suggested that a VLED approach be used for individuals unsuitable or unwilling to undergo surgery.⁴⁷

The findings from the DiRECT study led to the rollout of a VLED program in primary care in the UK, in what was termed a “diabetes remission service”.⁴⁸ Despite the growing acceptance of the role of a VLED program for weight loss and type 2 diabetes treatment in adults, there remains significant hesitation in their use in youth (see sections, VLEDs in Clinical Practice and Safety of VLEDs in Youth). Although the available evidence appears promising, it remains limited compared with adult studies.

Guidelines for Use of VLEDs in Children and Adolescents

A 2020 review of guidelines for the dietary management of pediatric obesity found that all 28 guidelines recommend a multicomponent family-based lifestyle intervention including education relating to dietary change, physical activity and behavior change strategies as first-line therapy.^{11,49} If improvements in weight status and/or cardiometabolic health are not attained using this approach, progression to a more structured and intensive intervention is recommended.

In six of the 28 guidelines identified in the 2020 review, a food-based or meal replacement VLED is proposed as one of the intensive dietary strategies recommended to induce weight loss in children and adolescents with obesity and related comorbidity or severe obesity.¹¹ Specific guidance on the use of a VLED in clinical practice for pediatrics is provided in only one set of guidelines published by the Academy of Nutrition and Dietetics. These guidelines recommend a short-term VLED prescription (10–12 weeks) that is 600–800 kcal/day, high in lean protein (1.5 to 2.0 g/kg of ideal body weight), 20–25 g/day of carbohydrate, with 2 L/day of calorie-free fluid and a daily multivitamin, prescribed under the supervision of a multidisciplinary team.²⁸ A VLED may provide an intermediate step between conventional lifestyle intervention and bariatric surgery, particularly for adolescents with severe obesity.¹¹ However, the paucity of recent trials and lack of long-term data has limited the inclusion of this dietary approach into clinical practice guidelines. A broader evidence base is required to inform future guidelines for the management of pediatric obesity.

Guidelines for the management of type 2 diabetes in youth are largely based upon obesity management guidelines. A family-based multicomponent lifestyle intervention, delivered by a pediatric dietitian experienced in the management of type 2 diabetes, is recommended alongside medical management of type 2 diabetes in youth, often aiming for weight loss.^{12,14,15,50–52} The American Diabetes Association¹⁴ recommends intensive weight management as a component of the treatment plan for youth with type 2 diabetes but does not recommend a specific dietary approach. A carefully monitored and individualized VLED-based dietary intervention is recommended in some guidelines as a short-term (8–12 weeks) approach to achieve rapid weight loss and

improve glycemic control in adolescents with obesity and type 2 diabetes.^{50–52} Overall, guidelines highlight a lack of evidence relating to specific dietary approaches beneficial for the management of type 2 diabetes in youth, representing an important area for further research.^{14,50–52}

Guidelines for the use of dietary interventions in the management of pediatric obesity recommend screening for eating disorders prior to initiating treatment.⁴⁹ Similarly, the Australian Paediatric Endocrine Group recommends screening for disordered eating prior to the use of a VLED in adolescents with type 2 diabetes.⁵⁰ To the best of our knowledge, self-report questionnaires designed to screen for eating disorder pathology have not been well validated in children or adolescents with obesity or those seeking obesity treatment. A number of screening procedures have been suggested and are yet to be evaluated.⁵³

VLEDs in Clinical Practice

The hesitation in the use of VLED programs for the treatment of obesity and type 2 diabetes in young people likely, at least in part, stems from the unique clinical challenges that this age presents to health care professionals.

Motivation

Behaviour change within the current social context and environment is difficult. Yet on top of this, the adolescent brain may also lack the maturity to comprehend the future health benefits of weight loss and focus instead on immediate gratification.⁵⁴ This is supported by a 2018 review examining the viewpoints of adolescents with obesity who attended a weight management intervention which found that the motivation to lose weight was more often related to wanting to be “normal” and socially desirable as opposed to preventing health sequelae.⁵⁵ Goals and motivators for weight loss thus should be meaningful to the adolescent in the short-term. These may include the reduction in medication usage, even if temporary, or motivators such as increased clothing choices to attend social gatherings, reduced bullying, fewer unwelcome comments by family members, and material rewards for weight loss such as jewellery, games, or outings. Clinicians need to harness such motivating factors, utilizing motivational interviewing techniques, to assist the adolescent with acceptance of and adherence to this challenging energy restriction.

Side Effects

The low carbohydrate content of a VLED, and associated mild ketosis, can result in the manifestation of several expected but unpleasant side effects including constipation, fatigue, nausea, headaches or dizziness⁵⁶ and halitosis. Adolescents should be pre-warned of these, usually transient, side effects and encouraged to persevere with the VLED. Indeed, a high prevalence of similar side effects including fatigue, headaches and muscle cramps have been observed in adolescents presenting with obesity.⁵⁷ Therefore, it is unclear whether all side effects reported when following a VLED are solely related to the diet. The addition of a stool-bulking dietary fibre such as psyllium husk at commencement of a VLED may alleviate constipation.⁵⁸ Ensuring adequate fluid intake of an additional 2 litres in addition to the water added to the VLED products also aids in preventing constipation and headaches.

Barriers and Challenges to VLED Adherence

Adherence to VLEDs in adults is high⁵⁹ and easier than anticipated.⁵⁸ However, despite the previously described treatment advantages for young people, there are several barriers to their use in clinical practice (Table 3) and adherence may be more challenging compared to adults. In our clinical experience with youth with confirmed type 2 diabetes (aged 13–16 years at VLED commencement), common challenges with adherence to a VLED include taste or textural issues, limited variety of products, missing “real food”, and feeling isolated whilst family members or friends consume whole foods around them. Similar to adult studies,³⁸ adolescents also report difficulty attending social events while following a VLED. Ensuring adequate water is added to shakes or soups for a thinner consistency, or cooler water, may increase palatability. Additionally, a variety of

shakes, bars, soups, and puddings are available on the market and trialling different brands may reduce taste fatigue.³⁸

Some families may be faced with financial constraints, therefore the perceived added cost of purchasing VLED products in addition to the usual grocery bill may be a barrier to commencing or adhering to a VLED program. However, replacing all meals and snacks with meal replacement products available in Australia costs less than “real food”, based on average per capita food expenditure.³²

Facilitators to VLED Adherence

There are also several strategies that healthcare professionals and families can utilize to facilitate the young person’s ability to adhere to a VLED (Table 3). The provision of VLED products by the treating team and frequent contact with a healthcare professional facilitate low attrition rates.⁵⁸ Similar to what is reported in adult studies, in our clinical practice we have observed successful maintenance of the VLED when family members and friends are supportive of the adolescent by undertaking the diet with them, providing encouragement and/or not offering any additional foods.³⁸ Adolescents enjoy using technology as part of weight management interventions, therefore the use of calorie counting phone applications may assist adherence to the 800kcal per day limit.⁵⁵ Additionally, a combination of meal replacements and a food-based meal that is high in protein and non-starch vegetables adds variety and may increase palatability and acceptability. Similar to what has been described in a review synthesizing qualitative research on the experiences of adults with overweight or obesity using VLEDs for weight loss,³⁸ adherence may also be facilitated by meal planning, pre-preparing vegetables, drinking lots of water, navigating the practicalities of social outings, including looking at menu items in advance, and

Table 3 Potential Barriers to and Facilitators of the Use in Clinical Practice of Very-Low-Energy Diets to Treat Youth with Obesity and/or Type 2 Diabetes

Barriers	Facilitators
<ul style="list-style-type: none"> • Difficult to adhere to calorie restriction • Potential safety concerns not adequately addressed in research to date • Diet acceptability, ie limited food options and taste of meal replacements • Perceived unaffordability of meal replacement products • Difficulty attending social events 	<ul style="list-style-type: none"> • Frequent contact with health professional • Provision of VLED products • Support from family and peers • Technology, ie calorie counting phone applications • Well thought out meal plans • High water consumption • Planning for social outings

incorporating options such as no sugar soft drinks or flavored waters.

Safety of VLEDs in Youth

Weight loss in children and adolescents is contentious due to concerns regarding possible impacts on psychosocial health. Indeed, children and adolescents with obesity and/or type 2 diabetes present with a range of psychosocial comorbidities including reduced quality of life and self-esteem and increased binge eating and depressive symptoms.^{57,60} However, a series of systematic reviews conducted by our team suggests improvements in psychosocial outcomes following health professional-led pediatric obesity treatment.^{61–63} Furthermore, the 2017 pilot study investigating the feasibility of using a VLED in the treatment of adolescents with type 2 diabetes also demonstrated improved quality of life following the intervention.³⁵ In adults, the DiRECT study showed that behavioral strategies are an important aspect of administering a VLED.⁴² Together, these findings highlight the need for an adult or young person to engage with a health professional when undertaking a VLED. Many adolescents with severe obesity have a weight that is beyond a healthy adult weight, emphasizing the need for weight loss in this group. In particular, weight loss is indicated in the presence of type 2 diabetes and may facilitate remission of diabetes.

The application specifically of a VLED for weight loss has additional concerns due to the restrictive nature of the diet. In addition to common expected side effects of a VLED, of major concern was the sudden deaths that were reported in adult studies published in the 1970s and 1980s following VLED use.^{64–66} It is likely that these deaths were related to severe nutritional inadequacies that are avoidable now due to the availability of nutritionally complete meal replacements. The 2019 systematic review evaluating studies implementing a VLED program for weight loss in children and adolescents found that safety was poorly described by included studies and suggested that future studies should ensure comprehensive safety data is collected and reported.²⁷ Despite the paucity of safety data, available data does not suggest that there are safety issues associated with the use of VLED programs to treat obesity and/or type 2 diabetes in youth.²⁷ However, long-term data are not available.

Nutritional inadequacies are common in restrictive diets, especially in children and adolescents who have increased requirements for several nutrients.⁶⁷ Although a VLED represents a severe energy restriction, VLEDs

are more commonly administered as meal replacements that are nutritionally complete. This is extremely advantageous, especially in children and adolescents who typically have a more narrow range of preferred food options. However, there are not any commercially available meal replacement products that have been developed based on the increased nutrient requirements of children and adolescents. Protein content in particular can vary between meal replacement products and should be calculated based on individual requirements.³² This should be considered when administering a VLED in a young person, with extra care taken to ensure that the prescribed diet is nutritionally complete, and consideration of the use of a multivitamin if the consumption of non-starchy vegetables is low. This emphasizes the need for dietitian input in VLED delivery in a young person with obesity and/or type 2 diabetes.

The Fast Track to Health study, currently underway in Sydney and Melbourne is conducting a 4-week VLED as a kickstart for weight loss in their trial comparing the effectiveness of an intermittent energy restricted diet and a standard hypocaloric diet approach.⁶⁸ This trial is collecting VLED safety data, including multiple psychobehavioral parameters, so will assist in addressing the literature gap on the safety of a VLED in adolescents.

Future Research

Although the data reported to date appear promising, the two trials in type 2 diabetes participants (one pilot study of $n=8$ and a chart review) and paucity of obesity treatment trials since 2000 (only two) do not provide sufficient evidence to support recommending a VLED program as a primary treatment strategy in clinical practice guidelines. Further investigation into the effectiveness of a VLED program to treat pediatric obesity and type 2 diabetes is needed in the form of larger, more robust clinical trials with an appropriate non-VLED treatment control group. Future trials should collect data on expected side-effects, growth, cardiac function, psychological wellbeing and acceptability of the diet to confirm the safety and feasibility of VLEDs in youth. Data collection should also continue beyond the intervention period to assess long-term safety and efficacy of VLED programs.

Recommendations for Clinical Practice

VLEDs appear to be a safe and effective method of short-term weight reduction when conducted under health professional

supervision. In the absence of usual carbohydrate intake, particular caution should be taken for youth with type 2 diabetes treated with insulin or other hypoglycemic agents. Input from a diabetes team is required to titrate medications and monitor for adverse outcomes including hypoglycemia. Involvement of a dietitian is highly recommended to ensure nutritional adequacy of the diet in the context of a very low calorie intake.

An important consideration for pediatric obesity treatment is that, if conventional treatment has been unsuccessful, a VLED may serve as an intermediate step between conventional lifestyle therapy and bariatric surgery. However, in pediatric type 2 diabetes treatment, a VLED program appears most effective if administered as close as possible to diagnosis, preferably within 6-months, with the potential to reverse the pathology of type 2 diabetes, at least in the short-term. Incorporation of the available evidence base for the use of VLED programs into clinical practice guidelines would be helpful to support the appropriate use in these populations. Details of diet composition, as well as suggestions for health professional monitoring should also be included in guidelines to direct clinicians on how to safely administer a VLED.

Conclusions

Available data suggest that, for the treatment of youth with obesity, VLEDs are effective for weight loss and have additional benefits for the treatment of type 2 diabetes including improved glycemic control and reduced medication requirements. However, lack of sufficiently powered, long-term trials and limited recent data, including comprehensive safety monitoring, contributes to hesitation of their use in clinical practice.

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy

Dovepress

Publish your work in this journal

Diabetes, Metabolic Syndrome and Obesity: Targets and Therapy is an international, peer-reviewed open-access journal committed to the rapid publication of the latest laboratory and clinical findings in the fields of diabetes, metabolic syndrome and obesity research. Original research, review, case reports, hypothesis formation, expert opinion

and commentaries are all considered for publication. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/diabetes-metabolic-syndrome-and-obesity-targets-and-therapy-journal>
