Background: Cataract surgery is mainly performed under topical anesthesia achieved either by tetracaine solution (0.5%–1.0%) or gel (0.5%), or by 2% lidocaine gel. This paper reviews the current knowledge about these two drugs, with special emphasis on a published prospective comparison between them.

Methods: The main pharmacological aspects of topical anesthetic agents are summarized, explaining the difference between the ester (tetracaine) and the amide (lidocaine) compounds. Tetracaine is available as single-use eye drops, or as a multidose gel containing benzalkonium chloride, a preservative not contained in the multidose lidocaine gel. A literature search was performed, using “tetracaine”, “tetracaine gel”, “lidocaine”, “lidocaine gel”, “lidocaine jelly”, and “cataract surgery” as keywords, and compiling cross-references. A total of 25 studies were identified and included in this review. Of them, seven were uncontrolled studies describing different experiences with the drugs of interest, and 18 were controlled studies. Six studies directly compared tetracaine eye drops or gel with lidocaine gel before cataract surgery.

Results: Both tetracaine solution and gel and lidocaine gel proved to be effective in providing analgesia before cataract surgery. Both drugs were comparable with needle injection anesthesia when intracameral lidocaine was added to topical treatment. Direct comparisons indicate better activity for tetracaine when used at the 1% concentration in single-dose units, or in the gel form at a 0.5% concentration. Patients showed a slight preference for the agent that caused the least discomfort when administered (lidocaine), while the surgical complication rate and the surgeon satisfaction were the same with either drug.

Conclusion: Tetracaine solution and lidocaine gel were equally effective in providing topical anesthesia for cataract surgery in the published studies. Tetracaine was found to be better than lidocaine only if augmented by either increasing the concentration to 1% (solution) or by increasing the penetration by adding benzalkonium chloride (gel).

Keywords: tetracaine, tetracaine gel, lidocaine, lidocaine gel, cataract surgery

Introduction

Cataract surgery consists of the replacement of the natural lens of the eye that has become cloudy with a new and transparent intraocular lens. It is the most frequent surgical procedure performed in the world, with a yearly rate approaching 1% of the entire population in Western countries.¹ The huge number of procedures performed requires a specific approach to management, and several improvements have been implemented in the past for this type of surgery. The eye incision decreased from 12 mm to 2.2 mm with the development of phacoemulsification and foldable intraocular lenses that are injected into the eye through special delivery systems. The procedure

is bloodless, because conjunctival incisions are no longer performed. Immobilization of the eye is not required, in that the surgeon can directly stabilize the eye by two instruments inserted 90° apart through two small incisions. The procedure lasts only 10–15 minutes in uncomplicated cases, with a very high success rate. Intraoperative and postoperative complications are very low, with the most feared one being endophthalmitis, which is well below 0.1%.² Cataract surgery is performed on an outpatient basis, and bilateral simultaneous surgery has been advocated.³

As a result, the retrobulbar or peribulbar needle anesthesia that had been used for more than a century was almost entirely abandoned about 15 years ago in favor of a new type of anesthesia, which only requires application of anesthetic drops.^{4,5} Topical anesthesia has been adopted in cataract surgery because there is no blood in cut or touched tissues that could remove the anesthetic drug, eyeball akinesia is no longer required, the procedure is usually short, additional anesthesia by either drop or needle can be applied at any time, and there is no risk of globe perforation by needles.^{6,7}

Anesthetics topically applied to the eye act directly on the corneal epithelium and stroma, and the portion of drug penetrating into the anterior chamber suppresses pain arising from the iris and ciliary body. The duration of effect of topically applied anesthetics depends on the properties of the drug used. Usually it lasts up to 15–20 minutes for the commonly used agents, but eye drop instillation or intracameral irrigation can be repeated at intervals during surgery if needed. The intraocular muscles are affected by topical/intracameral anesthesia, producing mydriasis, but there is no way to block extraocular muscles or to obtain akinesia of the eyeball.

The advantages of topical anesthesia over periocular injections include not only a higher safety level, but also better consistency of analgesia during surgery and lower intraocular pressure. Furthermore, the limited amount of drug used limits the general side effects commonly observed with local anesthesia.^{8,9} The return of sensitivity soon after surgery allows prompt discovery of any unexpected ocular pain suggesting complications.

Almost all the existing anesthetic drugs have been employed topically for cataract surgery.¹⁰ From the very beginning, we understood that only unpreserved drops were effective in practice, because drug preservatives caused temporary swelling of the corneal epithelium that prevented a clear view of the details of surgery.^{11,12} Therefore, some preparations became more popular, with different opinions and preferences across surgeons. Because not all of them are available across countries, the availability and selection

is somewhat limited. In this review, we focus on tetracaine solution and on lidocaine gel, because these two drugs represent the prototype of their category, and are currently the most widely used in the world.

Pharmacology

The sensitive terminations of the fifth cranial nerve are concentrated in the cornea and ciliary body in the anterior part of the eye. These fibers are generally nonmyelinated type A-delta and type C. They are able to transmit the sensations of pain, temperature, and touch, and are blocked by lower concentrations of drugs in comparison with motor fibers. The number of nerves involved determines the level of pain, and for this reason corneal abrasions are far more painful than corneal penetrations. To suppress pain, sensitive nerves have to be blocked by anesthetic agents along the nerve itself, or at its sensory terminations. Sensory termination block is the most important feature of topical anesthesia. It involves the inhibition of sodium channels at nerve endings or receptors by the anesthetic agents, thus blocking the production (and not the transmission) of nervous impulses.

Surface anesthetics used in ophthalmology are tertiary amines composed of an aromatic hydrophobic ring, usually benzene, and an amidic hydrophilic group, with an ester (proparacaine, tetracaine, benoxinate) or an amidic (lidocaine, etidocaine, mepivacaine, ropivacaine) intermediate chain.¹³ The properties of the drug (potency, onset and duration of action, selectivity) are determined by the chemical configuration of the two ends of the molecule. The anesthetic agents useful in clinical practice are unstable in their amine form and are insoluble in water. Therefore, they are prepared as salts that are stable in solution at relatively acidic pH. The low pH of commercially available solutions is the main cause of the burning sensation perceived on first eye drop application. After topical application in the conjunctival sac, the compounds have to be in the nondissociated form to cross the tear film and cornea, and to return to the dissociated form at nerve endings or axons to exert their anesthetic activity. The chemistry of body fluids and the activity of tissue enzymes favor these passages. The ester compounds are rapidly hydrolyzed by plasma esterases and to a lower extent by tissue esterases. The amide compounds are degraded more slowly in the liver, and therefore are endowed with a longer duration of action (Table 1).¹³

General side effects and the potential risks of needle injections are avoided by topical anesthesia, but local side effects can still occur. Inhibition of cellular sodium channels can cause some swelling of the corneal epithelium, especially in older patients, with the possibility of superficial

Table 1 Surface anesthetic agents that have been used in cataract surgery

Agent	Concentration (eye drops)	Action (minutes)		pH (25°C)	pKa	% base (pH 7.4)
		Onset	Duration			
Ester compounds						
Tetracaine	0.5%–1.0%	0.5	10–15	4.5–6.5	8.5	≈ 15
Tetracaine gel	0.5%	0.5–1	10–20	4.5–6.5	8.5	≈ 15
Proparacaine	0.5%	0.25	5–10	5.0–6.0	3.7	≈ 75
Benoxinate	0.4%	0.25	5–10	5.0–6.0	2.2	≈ 80
Amide compounds						
Lidocaine	4.0%	2–5	15–20	6.0–6.5	7.9	≈ 25
Lidocaine gel	2.0%	3–5	20–25	6.0–7.0	7.9	≈ 25
Bupivacaine	0.5%–2.0%	5–10	20–30	4.5–6.0	8.1	≈ 15
Ropivacaine	1.0%	2–5	15–20	5.0–6.5	8.1	≈ 15
Mepivacaine	2.0%	1–3	10–15	5.5–6.0	7.6	≈ 40

punctate keratitis.¹¹ When preservatives are added to the solution, epithelial toxicity is even more pronounced.¹² Anesthetic interruption of the blinking reflex increases this local toxicity and it is recommended that patients keep their eyes closed after bilateral instillation. These epithelial side effects can reduce corneal transparency during surgery, and warrant reduction of eye drop instillation and adjunctive intracameral anesthetic irrigation. Some of this toxicity can last a few days after instillation, slightly affecting vision.

Tetracaine solution

Tetracaine was the first anesthetic used topically for cataract surgery,⁴ and is still one of the most widely used. It is available in some countries at concentrations between 0.5% and 2%. After eye drop application, it rapidly penetrates the cornea, and especially if the pH has been adjusted to approach the tear film pH (7.6–7.8). It begins to take action within one minute and lasts for 10–15 minutes. Tetracaine is considered more toxic to the corneal epithelium than other agents, and therefore excessive application should be avoided.

The first clinical reports of tetracaine in cataract surgery appeared in 1993.^{14–16} Although preliminary in many aspects, those early works pointed out the most important features of topical anesthesia, ie, efficacy of the analgesia obtained, a possible decrease of corneal transparency during surgery, a steady rate of surgical complications as compared with peribulbar injections, positive acceptance from the patient point of view, early recovery of vision, and a lack of the obvious risks of needle injection. Since then, countless papers on topical anesthesia have appeared, outlining many different aspects of the procedure. Large field studies demonstrated topical anesthesia to be safe and effective from a population-based perspective, and demonstrated it to be suitable for use by inexperienced surgeons.^{17,18}

Despite this wide demonstration of validity, many variations of the treatment schedule have been proposed to address local needs and the opinions of patients and surgeons. In some instances, topical anesthesia was augmented by subconjunctival or periocular injections,¹⁹ mainly reflecting some difficulty in changing surgeon mentality and in establishing new relationships with the patient in the operating room.^{20,21}

Clinical studies of topical tetracaine anesthesia in cataract surgery include investigations performed to demonstrate the efficacy and safety of the procedure, as shown in Table 2. Interestingly, the conclusions of early smaller investigations^{22,23} were confirmed later on by larger studies^{24,25} concluding that topical anesthesia with tetracaine can be considered safe and effective in cataract surgery. However, adjunctive intracameral injection of lidocaine 1% significantly influenced one of the studies, and was probably determining the lack of pain when complications prolonged surgery.

Controlled trials comparing topical tetracaine with other types of anesthesia were also carried out (Table 3). Those studies demonstrated that tetracaine eye drops alone were less effective than tetracaine reinforced by intracameral lidocaine or by systemic acetaminophen.^{26–28} Tetracaine eye drops alone were also inferior to peribulbar or retrobulbar needle injections.^{29,30} However, the anesthetic efficacy of tetracaine eye drops plus intracameral lidocaine was the same as that of peribulbar injections.³¹ Interestingly, these studies confirmed the importance of pH of the solution in preventing pain from instillation.³²

Lidocaine gel

Amide-bound lidocaine is also one of the most utilized surface anesthetics in ophthalmic surgery, and is the most widely used for intracameral irrigation.³³ It is available in concentrations of 1%–4%, the unpreserved preparation being preferred because

Table 2 Uncontrolled studies of tetracaine eye drop anesthesia in cataract surgery

Author	Patients (n)	Concentration	Additional treatment	Primary outcome	Secondary outcome
Fichman ²²	100	0.5%	None	Blood pressure, heart and respiration rate unchanged	No need for intravenous sedation
Hoh et al ²³	20	1.0%	None	Quick visual recovery after the first 2 hours	
Monestam et al ²⁴	736	1.0%	None	Eye pain 1.8% Poor cooperation 1.1%	Posterior capsule rupture 5.2%
Irle et al ²⁵	1010	0.5%	1% lidocaine intracameral	Intraoperative pain (0–10): 1.62	Complications (0.5%) did not increase pain

of its better local tolerability. The instillation is rather painful because the pH of the solution is usually lower than 6. Intraocular penetration depends on the pH of the solution, and can be increased by repeating instillations.^{34,35} The advantages of lidocaine include a longer duration of action that might be useful in avoiding having to repeat instillations during surgery. However, postsurgical dry eye sensation³⁶ might be higher due to the very prolonged anesthetic effect.

The gel formulation of lidocaine is widely used in anesthesiology, otolaryngology, and urology at the 2% concentration, and has been used in ophthalmology for cataract surgery for several years.¹⁰ Gel formulations of drugs are considered better

for prolonging contact with the eye structures because they are not immediately washed out at the beginning of surgery. In addition, their drying effect on the ocular surface during surgery might be lower than that of aqueous solutions.³⁷

Several uncontrolled trials performed during the last 15 years established the value of lidocaine as topical anesthesia for cataract surgery (Table 4).^{38–41} All these studies pointed to a lack of need for additional anesthesia, with the exception of Waheeb who needed to use sedation in 2% of patients.⁴¹ In this study, phaco tip insertion was perceived as painful by patients, and this suggests limiting any pressure increase in the anterior chamber during phacoemulsification with topical anesthesia.

Table 3 Randomized studies of tetracaine topical anesthesia in cataract surgery

Author	Patients (n)	Study	Control Study versus control	Primary outcome Study versus control	Secondary outcome	P value
Carino et al ²⁶	60	0.5% tetracaine	0.5% tetracaine plus intracameral 1% lidocaine	Pain score (0–3) higher at surgery	Surgeon satisfaction (1–5): lower No patient preference	$P < 0.019$ for pain score $P < 0.001$ for surgeon satisfaction
Ho et al ²⁷	124	0.5% tetracaine	0.5% tetracaine plus intracameral 1% lidocaine	Intravenous midazolam equally required in both groups Less intravenous fentanyl required in the intracameral group	No systemic complications	P not significant
Kaluzny et al ²⁸	160	0.5% tetracaine	0.5% tetracaine plus 1 g oral acetaminophen	Pain score (0–10) higher at surgery and postoperatively	No difference in patient behavior No significant adverse events	$P < 0.01$ for pain at surgery and postoperatively
Johnston et al ²⁹	81	1.0% tetracaine	Peribulbar anesthesia	Pain score (0–10) lower at anesthesia higher at surgery same postoperatively	Same patient satisfaction	$P = 0.03$ for pain at anesthesia
Rüschen et al ³⁰	28	1.0% tetracaine	Peribulbar anesthesia	Satisfaction score (0–3) lower than peribulbar	One peribulbar injection	$P < 0.01$ for patient satisfaction
Fazel et al ³¹	564	0.5% tetracaine plus intracameral 1% lidocaine	Retrobular anesthesia	Pain score (0–6): same in the two groups	Same surgical complications in the two groups Complications from needle injections	P not significant
Hamilton and Claoue ³²	40	1.0% tetracaine	0.5% Proxy-methacaine	Pain score (0–10) higher at instillation same at surgery same postoperatively	No additional anesthesia No intravenous sedation	$P < 0.01$ for pain at instillation

Table 4 Uncontrolled studies of lidocaine anesthesia for cataract surgery

Author	Year	Patients (n)	Concentration	Additional treatment	Primary outcome	Secondary outcome
Assia et al ³⁸	1999	52	2%	None	Mean pain score (0–10): 0.72 ± 1.47	No additional anesthesia required
Kwok et al ³⁹	2006	41	2%	None	Aqueous humor concentration	Pain score (0–6): Median: 1
Von Jagow et al ⁴⁰	2007	45	2%	Intracameral 1% lidocaine	Visual acuity at 4 hours: 0.68 ± 0.18	Visual acuity at 1 day: 0.9 or better in >60%
Waheeb ⁴¹	2010	300	2%	Benoxinate 0.4% drops	No pain 85% Moderate pain 13% Sedation required 2%	Discomfort from high pressure in anterior chamber

Studies of lidocaine gel (or jelly) were carried out in the same time frame (Table 5). In a controlled trial, Koch found that lidocaine gel was equivalent to proparacaine drops, and was better only when applied a second time immediately before surgery.⁴² Bardocci et al⁴³ found higher aqueous humor drug levels after use of the gel than after drop application, but those levels were not related to pain sensation in their study, a conclusion that contradicted a previous study of ours.³⁵ Another two studies contributed to establishing the place of lidocaine gel in anesthesia for cataract surgery, ie, Sekundo et al⁴⁴ found it inferior to sub-Tenon injection and Soliman et al⁴⁵ found it superior to bupivacaine or benoxinate drops. None of these studies identified any complications arising from lidocaine gel application, but the importance of the low pH in causing burning sensation was confirmed.⁴⁵ For this reason, sometimes another agent gentler on the eye surface is used for reasons of patient comfort.⁴²

Comparative studies

A comparison of the efficacy and safety of tetracaine eye drops and lidocaine gel as anesthetic agents for cataract surgery could help surgeons in the selection of the agent

most suitable for specific techniques in a particular group of patients. A total of six comparative studies published between 1999 and 2010 were found in the literature, and are listed in Table 6. As early as 1999, Barequet et al found the efficacy of 0.5% tetracaine and 2% lidocaine gel to be similar before and after surgery, but there was a greater need for additional anesthetic drops during surgery with tetracaine.⁴⁶ In a larger study published in the same year, Harman was not able to detect any difference between the anesthetic efficacy of tetracaine eye drops and lidocaine gel, even after measurement of systemic blood pressure, that could be a sign of anxiety and of unreported pain.⁴⁷ The same conclusion was reached by Amiel and Koch in 2007, who considered 100 patients operated on while using the two drugs, both in gel form.⁴⁸ In their study, intracameral anesthesia was required in only one patient who had received lidocaine gel, a case too anecdotal to contradict the findings of Bardocci et al⁴³ regarding better penetration of the drug after gel application.

Most of these studies utilized a visual chart for scoring pain and other sensations. Visual charts only require the patient to set a point between minimum and maximum,

Table 5 Randomized studies of lidocaine gel anesthesia in cataract surgery

Author	n	Study	Control	Primary outcome Study versus control	Secondary outcome Study versus control	P value
Koch ⁴²	180	2% lidocaine gel once or twice plus 1% proparacaine drops	1% proparacaine with or without 1% lidocaine intracameral	Lidocaine gel better than drops only if applied twice	Intracameral 1% lidocaine the best adjunct agent	$P < 0.01$ between gel twice applied and drops
Bardocci et al ⁴³	107	2% lidocaine gel	4% lidocaine drops	Pain (0–10) higher with drops Aqueous humor levels higher with gel	No correlation between aqueous humor levels and pain score	$P < 0.001$ for pain $P < 0.001$ for aqueous humor levels
Sekundo et al ⁴⁴	100	2% lidocaine gel 1% lidocaine intracameral	sub-Tenon 2% lidocaine	Median pain score higher with gel	10% in the gel group converted to sub-Tenon	$P < 0.0001$ for pain
Soliman et al ⁴⁵	90	2% lidocaine gel 0.4% benoxinate drops	Bupivacaine 0.5%	Lidocaine gel worse at instillation, better at surgery	Conversion to sub-Tenon lower for lidocaine and bupivacaine	$P < 0.001$ for pain and for patient satisfaction

Table 6 Comparisons between tetracaine eye drops and lidocaine gel in cataract surgery

Author	n	Tetracaine	Lidocaine	Primary outcome	Secondary outcome	P value
				Study versus control	Study versus control	
Barequet et al ⁴⁶	25	0.5% drops	2% gel	Corneal sensitivity (0–6): Before instillation: 5 versus 6 5 minutes post instillation: 0 versus 0 After surgery: 0 versus 0	Need for additional anesthetic drops: Tetracaine 31% Lidocaine 17%	$P < 0.01$ for additional drops
Harman ⁴⁷	100	0.5% drops	2% gel	Same pain reported by the two groups	Same systolic blood pressure	P not significant
Amiel and Koch ⁴⁸	100	0.5% gel	2% gel	Same pain scores in the two groups	1 patient with lidocaine required intracameral anesthesia	P not significant
Tsoumani et al ⁴⁹	51	0.5% drops	2% gel	Same pain score in the two groups: 4.19 ± 2.32 versus 3.88 ± 2.72	Males and not accompanied patients showed less pain	P not significant
Irlle et al ⁵⁰	111	1.0% drops	2% gel	Pain score lower with tetracaine (1.77 versus 2.22)	“Negligible pain” 84% with drops, 74% with gel	$P = 0.043$ for pain score
Chalam et al ⁵¹	122	0.5% gel	2% gel	Pain score lower with tetracaine: 0.70 ± 0.31 versus 1.8 ± 0.4 with lidocaine	Same patient comfort Same surgeon satisfaction	$P < 0.001$ for pain score

without the need to answer questions. Their advantages are their simplicity and the numeric outcome, but excessive simplicity fails to consider external influencing factors. As pointed out by Tsoumani et al,⁴⁹ pain sensations are greatly affected by factors that are not related to the actual amount of pain perceived during surgery. Helped by psychologists, they discovered that males complained less than females, and that the presence of accompanying persons was associated with more pain, with the differences being statistically significant. Therefore, many variables should be considered when planning or reviewing small sample studies. For this reason, it may be difficult to detect small differences in pain using a visual scale, unless a very large number of eyes are recruited.

A difference between the efficacy of the two drugs was encountered in two studies. After studying 111 patients, Irlle et al found better activity for tetracaine eye drops, with a lower pain score at surgery (1.77 versus 2.22, $P = 0.043$).⁵⁰ Negligible pain was reported by 84% with tetracaine and by 74% with lidocaine (not statistically significant).⁵⁰ However, the tetracaine concentration used was 1.0%, which is double that used by other investigators. The second study published in 2009 by Chalam et al demonstrates the superior effect of tetracaine 0.5% versus lidocaine 2% gel,⁵¹ but a gel preparation of both compounds was used. Although no comparison between tetracaine drops and tetracaine gel was published, this might suggest better efficacy of the gel formulation. The presence of benzalkonium chloride in the gel, a preservative agent that damages the corneal epithelium and improves drug penetration, is a probable explanation for the better results with tetracaine in this study.

Safety

The ocular surface may be affected by topically applied drugs. Although most of the impairment takes place following prolonged exposure, as is the case for glaucoma medications, some damage might also come from short-term exposure, like that of anesthetic agents applied before cataract surgery. To avoid damage coming from preservatives, often causing epithelial swelling with decreased visibility,¹² single-use vials are preferred. Tetracaine eye drops are available as single-use vials, but the multidose gel preparation contains several nonactive chemical compounds, including benzalkonium chloride, that might affect the ocular surface. Lidocaine gel is also not available in single-use units, and the available preparations usually contain methylparaben, propylparaben, hypromellose, and sodium hydroxide and/or hydrochloric acid to adjust the pH to 6.0–7.0. Despite the several components, no side effects on the ocular surface have been reported that could be attributed to use of either tetracaine or lidocaine gel. On the contrary, improved wetting of the corneal surface has been reported with lidocaine gel.³⁷ The safety of surgery as determined by complication rates also appears to be the same with either tetracaine or lidocaine. No paper has reported any difference concerning intraoperative complications, suggesting that both drugs are suitable as anesthetic agents for cataract surgery.

Topically applied tetracaine is rapidly absorbed by tissues and is rapidly degraded by tissue esterases. In contrast, topically applied lidocaine is absorbed by tissues and transferred to the liver where degradation takes place. However, systemic levels of lidocaine following topical/intracameral administration were always found to be very

low and no systemic activity is expected during routine cataract surgery.⁵²

Patient and surgeon perspectives

Not surprisingly, patients were delighted by the advent of topical anesthesia for cataract surgery. Retrobulbar or peribulbar needle injection was the most feared part of the procedure, and general sedation was required more to administer the anesthesia than to perform surgery. As a consequence, sedation was discontinued soon after discontinuing the injections. The preference for topical anesthesia occurs despite the discomfort occasionally reported during surgery and in the postoperative period as compared with peribulbar injections.⁵³

From published comparisons, we may argue that patients have no preference for tetracaine eye drops or lidocaine gel as an anesthetic agent, but a detailed study of this issue and patient perspectives is not available. Pain on instillation might be greater for tetracaine because of the lower pH, but with a rapid onset of analgesia as a result of reduced stinging.

Surgeons need topical anesthesia for cataract surgery for two main reasons. First, because this is a high-volume activity, repeated instillations might be a problem in a busy practice, so a gel preparation of the active compound might be preferred. Second, patients are required not to react during surgery, and so far adjunctive intracameral lidocaine either routinely or occasionally both with tetracaine and with lidocaine has proven to be effective in obtaining almost the same level of analgesia as that of peribulbar injections.^{31,44,48}

Conclusion

At the moment we can conclude that both topically applied tetracaine solution and lidocaine gel are equally effective in providing analgesia for cataract surgery. Tetracaine, usually employed at the 0.5% concentration, was found to be better only when applied at the 1.0% concentration or in the form of gel. Tetracaine has the disadvantages of more stinging at first instillation and of requiring repeated applications. However, its shorter duration of action on the corneal nerves might reduce postoperative dry sensations. Lidocaine gel has the advantages of a single application and better wetting of the cornea, and might be preferred when prolonged surgery is anticipated. However, the more prolonged duration of action on the corneal nerves might increase the dry eye sensation in the immediate postoperative period. Both drugs have a definite place in ophthalmic surgery, and at the moment the surgeon's choice between them will depend more on personal preferences than on published results.

Open Access Surgery

Publish your work in this journal

Open Access Surgery is an international, peer-reviewed, open access journal that focuses on all aspects of surgical procedures and interventions. Patient care around the peri-operative period and patient outcomes post surgery are key topics. All grades of surgery from minor cosmetic interventions to major surgical procedures are covered. Novel techniques
