Background: Endoscopic valve implantation is an effective treatment for patients with advanced emphysema. Despite the minimally invasive procedure, valve placement is associated with risks, the most common of which is pneumothorax. This study was designed to identify predictors of pneumothorax following endoscopic valve implantation.

Methods: Preinterventional clinical measures (vital capacity, forced expiratory volume in 1 second, residual volume, total lung capacity, 6-minute walk test), qualitative computed tomography (CT) parameters (fissure integrity, blebs/bulla, subpleural nodules, pleural adhesions, partial atelectasis, fibrotic bands, emphysema type) and quantitative CT parameters (volume and low attenuation volume of the target lobe and the ipsilateral untreated lobe, target air trapping, ipsilateral lobe volume/hemithorax volume, collapsibility of the target lobe and the ipsilateral untreated lobe) were retrospectively evaluated in patients who underwent endoscopic valve placement (n=129). Regression analysis was performed to compare those who developed pneumothorax following valve therapy (n=46) with those who developed target lobe volume reduction without pneumothorax (n=83).

Finding: Low attenuation volume% of ipsilateral untreated lobe (odds ratio [OR] =1.08, $P=0.001$), ipsilateral untreated lobe volume/hemithorax volume (OR =0.93, $P=0.017$), emphysema type (OR =0.26, $P=0.018$), pleural adhesions (OR =0.33, $P=0.012$) and residual volume (OR =1.58, $P=0.012$) were found to be significant predictors of pneumothorax. Fissure integrity (OR =1.16, $P=0.075$) and 6-minute walk test (OR =1.05, $P=0.077$) were also indicative of pneumothorax. The model including the aforementioned parameters predicted whether a patient would experience a pneumothorax 84% of the time (area under the curve =0.84).

Interpretation: Clinical and CT parameters provide a promising tool to effectively identify patients at high risk of pneumothorax following endoscopic valve therapy.

Keywords: endoscopic lung volume reduction, COPD, emphysema, pneumothorax, valve therapy

Introduction

Endoscopic valve therapy has evolved as a new therapeutic modality in patients with advanced chronic obstructive pulmonary disease (COPD) and emphysema. This technique involves the implantation of one-way valves in the emphysematous lung lobe. By allowing the air to exit during expiration, the valves lead to target lobe volume reduction (TLVR), whereby a complete lobar atelectasis represents the optimal result.

The first randomized controlled trials (RCTs), known as VENT ("Endobronchial Valves for Emphysema Palliation Trial") and Euro-VENT, demonstrated encouraging results concerning the safety and effectiveness of this procedure.^{1,2} Adverse events, including COPD exacerbations, pneumonia, mild hemoptysis, hypercapnia, and pneumothorax, were observed, but the rate of serious complications did not differ between the treatment and control groups. In these RCTs,

the pneumothorax rate was 4.2% and 4.5% at 90 days following the intervention.

In VENT and Euro-VENT, complete interlobar fissures in the preinterventional multidetector computed tomography (MDCT), which is a surrogate for low interlobar collateral ventilation, and lobar occlusion were found to be predictors of a meaningful clinical outcome following valve placement. Therefore, only a complete occlusion of the target lobe in patients with low collateral ventilation was recommended; this was reevaluated in two recently published RCTs, the BeLieVeR-HIFI study and STELVIO.^{3,4} These trials confirmed the efficacy of valve therapy but revealed an increased pneumothorax rate of 8%–18%. It is likely that a parenchymal rupture of the ipsilateral untreated lobe due to rapid expansion in the case of volume reduction of the treated lobe is the reason for the pneumothorax. In further trials, the authors reported even higher pneumothorax rates of 25%, 23%, and 20%.^{5–7} Thus, the optimized patient selection is not only associated with improved outcomes following valve placement but also implies a higher risk of pneumothorax. Completeness of the fissure is particularly considered to support optimized outcomes as well as the advent of pneumothorax.

As pneumothorax seems to occur only in patients with significant volume shift, it is assumed that they may nevertheless experience good clinical outcomes in case of persistent TLVR after recovering from pneumothorax.⁸ However, pneumothorax presents a severe complication that frequently requires chest tube insertion and is associated with immobilization, prolonged hospitalization, and further endoscopic or surgical interventions.^{9,10} Furthermore, tension pneumothorax may also present a life-threatening complication that may lead to a shift of the mediastinum and obstruction of venous return to the heart, compromising cardiovascular circumstances. Therefore, assessing the predictors of pneumothorax other than fissure integrity, which also predicts TLVR, is of great importance.

Methods

In this retrospective analysis, clinical and MDCT scan data of patients who underwent valve therapy were examined to determine predictors of pneumothorax following valve therapy. The protocol of this retrospective analysis was approved by the local Ethics Committee of Heidelberg (S-609/2012). The majority of the patients were treated within different prospective trials after written informed consent. As the data in this current analysis were retrospectively analyzed no further patient consent was required.

Subjects and clinical parameters

In this retrospective analysis, baseline clinical measures and MDCT scan data of 129 consecutive patients (mean age: 64 years, range 43–81 years, sex: 50% male) who experienced TLVR ($n=83$) or pneumothorax ($n=46$) following valve therapy between 2009 and 2013 were assessed. The mean forced expiratory volume in 1 second (FEV_1) was 0.8 ± 0.2 l ($32\% \pm 8\%$ predicted) and the mean residual volume (RV) was 5.6 ± 1.4 l ($257\% \pm 59\%$ predicted). All the patients experienced a complete occlusion of the target lobe by endobronchial (Pulmonx, Inc., Neuchatel, Switzerland) or intrabronchial valves (Olympus Corporation, Tokyo, Japan) at the Thoraxklinik at the University of Heidelberg. Prior to valve therapy, MDCT, including software analysis of the emphysema (YACTA, “yet another CT analyser”), and 99 m-Tcnetium perfusion scan were performed to identify the target lobe. Sixty-one patients (47%) experienced complete occlusion of the left lower lobe, 34 (26%) of the left upper lobe, 20 (16%) of the right upper lobe, 13 (10%) of the right lower lobe, and one (1%) of the right upper and middle lobes. TLVR was defined as lung parenchymal collapse with the development of a soft-tissue dense atelectasis at a lobar or segmental level on a follow-up chest X-ray or CT scan.

Clinical parameters prior to valve therapy and 3 months following pneumothorax, including vital capacity (VC), forced expiratory volume in 1 second (FEV_1), residual volume (RV), total lung capacity (TLC), and the 6-minute walk test (6-MWT), were extracted from the patients' records. Descriptive parameters (target lobe) were also evaluated.

MDCT parameters

The qualitative and quantitative MDCT parameters were assessed on preinterventional baseline MDCT scans (64-slice Somatom Definition AS64, Siemens Medical Solution, Forchheim, Germany); the CT protocol varied with reconstruction slice thickness of 1.0 (filter I40f), and doses of 100 kV, 117 mAs_{effective} or 120 kV, 70 mAs_{effective}. The qualitative MDCT parameters were visually assessed by one experienced chest radiologist. The quantitative CT measurements were obtained by using syngo.via software (Siemens Medical Solution), which provides automated three-dimensional quantifications for the assessment of emphysema. The mean lung density of the lobes, lobar volumes, low attenuation volumes (LAVs) and the lobar collapsibility were obtained. The LAV (lung volumes with attenuation values <950 Hounsfield units) and LAV% (the ratio of LAV to the volume of the region of interest) that

correlate with lung function parameters, visual CT emphysema scores, and the COPD assessment test were used to describe the extent and severity of emphysema.^{11–14}

Statistical analysis

Univariate logistic regression models were fitted to assess the association between each of the 41 variables and pneumothorax following valve therapy. We also assessed whether each continuous variable had a linear or quadratic association with pneumothorax in the logit scale. Stepwise forward regression model was fitted to assess the association between possible predictor variables and pneumothorax. Variables with a P -value <0.5 were included in the stepwise forward regression model in the most appropriate form (linear or quadratic).

The paired Student's t -test was used to compare within-group differences in qualitative parameters. P -values <0.05 were considered to be significant. Receiver operating characteristic curves were created using the final model of predictors.

Results

The patient characteristics of the 83 subjects with a radiologically confirmed TLVR (Figure 1) and those of 46 patients who developed pneumothorax (Figure 2) are presented in Table 1. On the baseline MDCT scans, fissure integrity varied from 80% to 100%. The fissure integrity was between 90% and 100% in 121 patients and between 80% and 90% in eight patients. Overall, the median of fissure completeness was 100% (interquartile range 98.3 to 100).

Figure 1 Multidetector computed tomography image.

Note: Lobar atelectasis of the right lower lobe following valve implantation.

Thirty-eight of the 46 patients (83%) who developed pneumothorax underwent chest tube insertion. In 18 patients (39%), valve explantation was necessary. Eight patients (17%) underwent additional video-assisted thoracoscopy to seal the fistula. Three months after recovering from pneumothorax, patients experienced slight, but not clinically relevant improvements in lung function parameters, exercise capacity and dyspnoe score (Table 2).

After the multivariable regression analysis (Table 3), the LAV% of the untreated ipsilateral lobe, the volume of the untreated ipsilateral lobe to volume of the hemithorax, the predominant type of emphysema, the presence of pleural adhesions, and the residual volume were variables that were independently associated with pneumothorax, adjusting for the target lobe; the 6-MWT and the fissure integrity were borderline non-significant. Thereby, residual volume (odds ratio

[OR]=1.58, $P=0.012$) and untreated ipsilateral lobe LAV% (OR=1.08, $P=0.001$) were associated with an increased risk of pneumothorax. In contrast, the presence of pleural adhesions (OR=0.33, $P=0.012$), the presence of panlobular emphysema (OR=0.26, $P=0.018$), and the volume of the untreated ipsilateral lobe to the volume of the hemithorax (OR=0.93, $P=0.017$) were associated with a decreased risk of pneumothorax. Finally, the 6-MWT (OR=1.05, $P=0.077$) and the fissure integrity (OR=1.16, $P=0.075$) tended to be associated with an increased risk of pneumothorax. The area under the curve using the full model with eight variables was 0.84. This indicates that it is possible to predict whether a patient would experience a pneumothorax 84% of the time (Figure 3).

Table 3 Predictors for pneumothorax following valve therapy

Pneumothorax	Odds ratio	95% confidence interval	P-value
Ipsilateral lobe LAV%	1.08	1.04–1.14	0.001
Predominant type of emphysema (panlobular vs centrilobular)	0.26	0.09–0.74	0.018
Pleural adhesion	0.33	0.13–0.83	0.012
RV (change per unit)	1.58	1.10–2.25	0.012
Volume of the untreated ipsilateral lobe to the volume of the hemithorax	0.93	0.87–0.99	0.017
6-MWT (per 10 m change)	1.05	1.00–1.10	0.077
Target lobe LLL (vs RUL)	0.28	0.06–1.33	0.108
Target lobe LUL (vs RUL)	0.95	0.19–4.74	0.954
Target lobe RLL (vs RUL)	0.23	0.03–1.83	0.165
Fissure integrity	1.16	0.99–1.36	0.075

Notes: Pneumothorax with subsequent severe bilateral subcutaneous emphysema 3 days following valve placement in the left lower lobe. The lung is reinflated after chest tube insertion.

Figure 3 ROC curve.

Note: Prediction of pneumothorax following endoscopic valve therapy using eight CT and clinical parameters with an AUC of 0.8367.

Abbreviations: CT, computed tomography; AUC, area under the curve; ROC, receiver operating characteristic.

Discussion

Endoscopic valve therapy has evolved as an effective therapy for patients with severe COPD and emphysema. It has been developed as a minimally invasive technique to achieve lung volume reduction with less morbidity and mortality than has been reported in lung volume reduction surgery.¹⁵ However, valve therapy is also associated with potential complications. Over the past several years, the rate of pneumothorax following valve insertion particularly increased due to modified patient selection. A complete fissure is not only a predictor of excellent outcome but also of pneumothorax. Pneumothorax occurring in 18%–25% in patients undergoing valve insertion is actually the most common complication following valve therapy.^{4–7}

To assess the risk of pneumothorax, we performed this retrospective analysis to determine the predictors of pneumothorax following valve insertion. As patients with TLVR and pneumothorax fulfill the criterion of complete interlobar fissure that is regarded as a prerequisite indication for valve therapy, we focused on both of these patient cohorts; the distinction between both these groups is crucial. As a result, the median of fissure integrity was 100%, which explains why fissure integrity was not found to be a statistically significant predictor of pneumothorax.

In this analysis, the LAV% of the untreated ipsilateral lobe, the volume of the untreated ipsilateral lobe to the volume of the hemithorax, the emphysema type, and pleural adhesions were significant CT predictors of pneumothorax. The higher the emphysematous destruction of the untreated ipsilateral lobe, the higher the risk of pneumothorax. The important role of the untreated ipsilateral

lobe can be explained by the development of pneumothorax following valve implantation. It is hypothesized that pneumothorax occurs by parenchymal rupture in the adjacent untreated lung lobe in cases of rapid TLVR. In contrast to expectations, panlobular emphysema was found to be a protective factor for the development of pneumothorax. Initially it was assumed that panlobular emphysema distribution would increase the risk, but exactly the opposite was actually found. The blebs and bullae that were assumed to increase the risk were also found to play no significant role in the development of pneumothorax. The finding of the protective character of a panlobular emphysema can not be sufficiently explained; possibly, the compliance of the lung tissue in the different emphysema types varies and may be associated with a different risk of pneumothorax. In addition, pleural adhesions were surprisingly found to be protective factors against pneumothorax. As a clinical predictor, the residual volume was a variable that was independently associated with pneumothorax, adjusting for the target lobe. The higher the residual volume, the higher the risk of pneumothorax. A high residual volume may be associated with a greater volume shift, increasing the risk of parenchymal rupture. In that model, all of these parameters would predict whether a patient would experience a pneumothorax 84% of the time.

One retrospective trial demonstrated that most patients experienced an improvement in clinical outcomes due to the lung volume shift despite pneumothorax.⁸ This finding was confirmed by another trial demonstrating a statistically beneficial outcome in patients who developed pneumothorax following valve therapy.¹⁶ However, only patients in whom lobar atelectasis could be observed after recovering from pneumothorax will experience an outstanding improvement in lung function parameters, while patients without a significant TLVR following pneumothorax will experience slight but not relevant clinical improvement. In this analysis, no relevant clinical improvement was achieved after the development of a postinterventional pneumothorax, but pneumothorax following valve therapy did not impair the clinical outcome. Thus, there are some controversial data related to outcomes following pneumothorax in valve patients, but most studies suggest that patients who develop TLVR despite pneumothorax will benefit. However, pneumothorax is associated with prolonged hospitalization and immobilization, leading to muscle wasting and often requiring further intervention, such as chest tube insertion or surgical intervention.

In one trial, bed rest and antitussive therapy successfully reduced the risk of pneumothorax following valve insertion.⁵ Forty patients who received modified medical care, including 48 hours of strict bed rest and 16 mg codeine if needed for cough up to three times a day, were compared to 32 patients with standard medical care following valve therapy. While eight patients from the standard medical care group developed pneumothorax during hospitalization, only two from the modified medical care group experienced pneumothorax ($P=0.02$). However, the number of treated patients in this study population was too low to allow a general statement for or against this modified postinterventional strategy.

Assessing the risk of pneumothorax helps to find the balance between efficacy and safety. Therefore, finding the predictors for pneumothorax is of great importance. The risk of pneumothorax of 18%–25% is accepted because the development of pneumothorax does not impair clinical patient outcomes. Nevertheless, the evaluation of valid prevention measures is crucial to minimize the risk of pneumothorax that presents a severe adverse event in patients with advanced emphysema.

In summary, pneumothorax is a commonly anticipated complication of valve therapy in patients with severe emphysema. Therefore, close monitoring following intervention is necessary. Patients with a high LAV% of the untreated ipsilateral lobe and a high residual volume are at particularly great risk of pneumothorax. A high volume of the untreated ipsilateral lobe compared to volume of the hemithorax, panlobular emphysema and pleural adhesions, however, were found to be protective. A thorough evaluation of the risks is essential to determine and discuss the therapy and risk–benefit profiles with the patient.
