Clinical question: What is the best treatment for tennis elbow?

Results: Despite a wealth of research, there is no true consensus on the most efficacious management of tennis elbow especially for effective long-term outcomes. Corticosteroid injections do show large pain-relieving effects in the short term but are associated with risks of adverse events and long-term reoccurrence. Advice with a “wait and see” approach is recommended as the first-line treatment in primary care for most cases. In the medium term physiotherapy and or low-level laser therapy may be effective.

Implementation: Rule out alternative diagnosis. Onward referral may be indicated if the condition does not resolve after 12 months.

Keywords: tennis elbow, corticosteroids, physiotherapy, laser therapy

Tennis elbow

Definition: Tennis elbow, also known as lateral epicondylalgia (LE) and often referred to as epicondylitis or tendinopathy clinically,1 has a complex underlying pathophysiology which is not well understood but is characterized by uncomplicated signs of localized pain over the lateral epicondyle which is made worse with resisted wrist extension and grip.2 The term epicondylitis has recently been considered a misnomer because a lack of inflammatory signs.

Etiology: The annual incidence of tennis elbow is 4 to 7 cases per 1000 patients, predominantly in patients aged 35 to 55 years.3,4 The condition affects between 1% and 3% of the population.5,6 is usually self-limiting, and lasts between 6 and 24 months.4 Twenty percent of cases persist for more than a year.7

Risk factors: Repetitive manual tasks, or handling of heavy loads (>20 kg) or heavy tools (>1 kg).8 Risk is increased by a working posture of arms raised in front of the body, coupled with repetitive forearm twisting or rotating motions. The risk is further increased by high gripping force.9 LE is also associated with computer use of more than 20 hours per week, a risk that increases in line with years of use.10

Economics: Up to 30% of patients report work absenteeism.

Level of evidence: Systematic reviews, meta-analyses, general reviews, and randomized controlled trials (RCTs).

Search sources: MEDLINE (PubMed), CINHAL, EMBASE, AMED, Web of Knowledge, SPORTDiscus, Cochrane Library, DARE, DHdata, PEDro.
Outcomes: From a patient perspective the main outcomes are:

- Pain relief at rest and on activity.
- Improved function.
- Reduced sick leave.
- Avoidance of adverse events.

These are frequently measured in the short (0 to 12 weeks), intermediate (13 to 26 weeks), and long term (≥52 weeks).

Consumer summary: Tennis elbow is a common, painful condition that generally occurs in middle-aged people and often prevents them from working or participating in their usual daily activities. Despite a large number of studies investigating an array of interventions, there is no favored evidence-based treatment for tennis elbow that gives anything beyond short-term pain relief. Corticosteroid injections do show large benefits in the short term, but can be painful and are associated with an increased risk of long-term recurrence, especially if more than one injection is given. There is some evidence that low-level laser therapy (LLLT) may be beneficial in the short term, although this is controversial and not always available as a treatment. Combined physiotherapy treatments give some medium-term relief slightly superior to advice and analgesics alone and show significantly better outcomes than steroid injections in the long term. For those patients who do not recover or respond to treatment in the long term, there is limited low-level support for injecting blood plasma, or for persistent and severe cases to undergo surgery. Advice with prescribed over-the-counter pain medication is recommended as the first-line treatment for most cases.

The evidence

Are injection therapies beneficial?

(a) Corticosteroid agents

Steroid injections are the most thoroughly investigated intervention. There are 4 systematic reviews,12-15 the most recent reporting 18 separate analyses from 12 trials (n = 1171 patients).14 Coombes et al14 concluded that there was strong evidence for the short-term benefit of corticosteroid injections across all outcome measures. Despite heterogeneity within the included trials which prevented pooling of some data for meta-analysis, consistent large effect sizes were seen in favor of corticosteroid injections compared with no intervention (“wait and see”), non-steroidal anti-inflammatory drugs (NSAIDs), physiotherapy, orthotic devices, and platelet-rich plasma (PRP) injections (reported in a separate review).16 These findings are in agreement with previous meta-analyses of the same subject12,13 and with a recent systematic review restricted to comparing corticosteroid injections with various (individual as opposed to combined) physiotherapy interventions.15 One exception to this was the comparison with NSAIDS, in which Gaujoux-Viala et al13 reported that corticosteroids were not better in the short term (n = 1113).

In the intermediate and longer term, Coombes et al14 reported strong evidence that corticosteroid injections are less beneficial and show more adverse responses than all other interventions. This is also in agreement with a previous analysis.7 The authors report a subanalysis, which included the variable quality of trials, and this did not alter their conclusions. Different doses and suspensions of corticosteroid did not alter outcomes, although repeated injections (average 4.3, range 3 to 6 over 18 months) were associated with poorer outcomes.14 Gaujoux-Viala et al13 also reported a sensitivity analysis for disease duration which suggested that steroid injections are more effective in acute and subacute tendonitis (duration <12 weeks) than in chronic disease, although the authors did suggest publication bias in favor of positive trials.

In the Coombes et al review,14 82% of trials using corticosteroid injections reported adverse events which affected 17% of patients (n = 72416; atrophy 38, pain 31, depigmentation 2, rupture 1). Another trial also reported high reoccurrence rates.17 A number needed to harm (NNH) of 26 for corticosteroid injections versus other commonly used treatments was reported.13 (The NNH is the number of patients who, if they received treatment, would lead to one additional person being harmed compared with patients who receive control treatments.19)

(b) Noncorticosteroid agents

Three systematic reviews have investigated the injection of noncorticosteroid agents, although the number of relevant studies included in each is very small.14,19,20 Coombes et al14 report the following results: sodium hyaluronate provided better pain relief at all outcome points than placebo injection (1 study; n = 165 intervention group). However...
the review authors noted that the placebo group (n = 166) in this study showed no improvement over 12 months, which is inconsistent with most other trials. No significant short-, intermediate-, or long-term effects were seen in 34 patients injected with glycosaminoglycan polysulfate (NSAID), or in the use of a sclerosing polidocanol versus a local anesthetic (lidocaine + epinephrine) (n = 32).

Rabago et al19 reviewed prospective case studies and controlled trials in respect of prolotherapy, polidocanol, whole blood, and PRP injections. They concluded that for LE which is refractory to conservative treatment, there is some limited pilot level evidence for the effectiveness of these therapies. For botulinum toxin a meta-analysis of 4 RCTs showed beneficial effects in the short term in pain reduction, but no effect on grip strength. No high quality studies have investigated long-term outcomes for any of these interventions.

No adverse effects were observed for sodium hyaluronate, lauromacrogol, prolotherapy, or PRP. Aprotinin was associated with itching and burning and botulinum toxin with weakness and paresis14 and pain at the injection site. Two studies of oral administration of analgesics produced inconclusive evidence. Usual adverse effect profiles of oral NSAIDS need to be considered.

Low-level laser therapy

Five systematic reviews were identified. The most recent (which covered tendinopathy generally22) utilized laser dose standards defined by the World Association for Laser Therapy (WALT) to assess adequacy of treatment within included studies.28 Twelve (from 25) included studies showed positive outcomes in the short term. In a previous review specific to LLLT for LE, 13 trials (n = 730 patients) showed reductions in pain and increased grip strength. (Comparably, corticosteroid injections show a more rapid onset in pain reduction and a larger effect size in the same period.) A subgroup analysis showed these effects were associated with narrowly defined doses of 904 nm wavelength LLLT (the treatment procedure is described as direct irradiation of approximately 5 cm² of the tendon insertion at the lateral elbow, with a dose of 0.25 to 1.2 joules, and mean output 5 to 50 mW. WALT also recommend peak pulse output >1 Watt, and power density of less than100 mW/cm² 30) and an added value effect of combining LLLT with exercise therapy. The authors suggest these positive findings are in spite of a negative publication bias across relevant LLLT literature. Only 2 studies present results for medium-term outcomes of LLLT which show positive effects observed up to 24 weeks.29 Although no adverse responses were reported for LLLT in either systematic review, this treatment may not be universally available.
Regimens of combined physical treatments

Two high-quality RCTs (n = 185, n = 194) (assessed using a modified PEDro scale outlined by Bisset et al) have investigated the effectiveness of packages of physiotherapy treatments (common elements include manual therapy, exercise, home exercise, and advice leaflets), with wait and see and steroid injection treatments. The pattern of response to treatments was similar in each study. Physiotherapy showed a significantly superior response compared with wait and see at 6 weeks (number needed to treat, NNT = 3) but there was no significant difference at 1-year follow up (NNT = 30) (NNT is defined as the number of patients who need to be treated in order to prevent one additional bad outcome; it is the inverse of the absolute risk reduction). Corticosteroid injections show usual short-term benefits but at 1 year an NNT = 4 in favor of physiotherapy is seen. An area under the curve analysis reported a significant advantage of physiotherapy over injections for all primary outcomes but only for pain-free grip compared with wait and see. Participants receiving physiotherapy needed less additional treatment than patients in other groups. Authors generally conclude that for most patients a wait and see approach is advisable, although physiotherapy packages can give short- to medium-term benefits without risks associated with steroid injections.

Which interventions are not proven?
Insufficient or inadequate evidence to support clinical recommendations is reported in Cochrane systematic reviews for the following treatments: oral NSAID, paracetamol, and codeine, orthotics, and acupuncture. Also for the following physiotherapy treatments delivered individually: exercise, manipulation or manual therapy, and ultrasound.

Table 2 shows relevant randomized controlled trials published after the latest systematic review.

Patients who fail to respond to conservative measures may be considered for surgery. A Cochrane review investigating the effect of surgery on lateral elbow pain did not identify any published controlled trials. However a more general review suggests this may be due to the indications for surgery being not well codified and many different operative techniques being available. A clear consensus on whether any given surgical procedure is superior is yet to be determined.

Which interventions are not likely to be beneficial?
Eleven of 13 pooled analyses undertaken as part of a Cochrane review found no significant benefit of extracorporeal shockwave therapy (ESWT) over placebo. A later review using a different method to assess treatment protocols reported a subgroup analysis indicating that positive results are associated with adequate treatment doses. However since evidence of efficacy is inconsistent, the United Kingdom National Institute for Health and Clinical Excellence guidelines state that the procedure should be used only for refractory tennis elbow with special arrangements for clinical governance, consent, audit, or research. In terms of adverse effects, ESWT may be associated with transient pain, nausea, and local reddening.

Conclusion
There is no true consensus on the most efficacious management of LE especially for long-term outcomes. Furthermore, most studies do not differentiate between clinical and statistical significant effects. Although corticosteroid injections do show large effect sizes in pain reduction, this

Management of tennis elbow

is seen only in the short term and the treatment is associated with risks of adverse events and long-term reoccurrence. If available, LLLT may be a safe alternative choice for beneficial but smaller short-term effects, especially if considered as an adjunct to exercise therapy. Combined physiotherapy treatment packages have been shown to give relief in the medium term but effects are only slightly better than advice and a wait and see approach in the long term. There is very limited evidence to support injection of blood plasma or botulium toxin in refractory LE. Advice with a wait and see approach are recommended as the first-line treatment in primary care for most cases.

The practice

Avoiding the pitfalls
The aim of treatment is to reduce pain and improve function, with minimal adverse effects.

Alternative diagnosis
Referred pain from the neck or shoulder and local elbow causes including olecranon bursitis, osteoarthritis, and posterior interosseus nerve compression.

Management
Most lateral epicondylagia can be managed in primary care setting. Indications for onward referral are given below.

Assessment
- Diagnosis is made following history and examination; further investigations are not required.
- A detailed social and occupational history is important in determining the cause of the LE and the impact. Occupations that involve repetitive and forceful arm actions of turning or lifting, such as plumbers, painters and decorators, bricklayers, and gardeners, are particularly at risk as are full-time keyboard users.
- Palpate around the affected elbow joint to identify the area of maximum pain usually over the common extensor tendon/lateral epicondyle.
- Look for pain in the elbow when pressure is applied while extending the wrist and holding against resistance, or when pressure is applied while twisting the forearm. There may be some forearm pain coupled with limited range of elbow movement; paraesthesia or pain above the elbow is unlikely.

Treatment
In the acute stage:
- Give advice on the self-limiting nature of the pathology if adequate steps to avoid aggravation of symptoms are taken.
- Give advice on modification of aggravating activities:
  - Avoid lifting, especially heavy weights,
  - Lift objects close to the body, with elbow bent and palm facing upwards
  - Avoid repetitive gripping and twisting activities,
  - Take regular breaks from all activities involving the upper limb,
  - Suggest the patient seek “light duties” which avoid tasks aggravating the condition at work if possible.
  - Offer analgesia or NSAID medication if clinically appropriate. Although evidence for analgesia and NSAID are inconclusive, patients may opt to try pain relieving medication.

If symptoms persist beyond 12 weeks but are less than 26 weeks, discuss other options including:
- Referral to physiotherapy for supervised and home exercise programs and manual therapy.
- Laser therapy (of the correct dose) could be considered.
- For short-term relief of severe pain consider corticosteroid injections. However consideration of long-term relapses and the likelihood of adverse effects should be discussed with the patient.

For recalcitrant tennis elbow (lasting more than 12 months) consider:
- Injections or PRP or prolotherapy.
- Surgery.

Indications for specialist referral
- A history of significant trauma.
- Failure to respond to conservative treatment after 12 months.
- Failure of symptoms to improve beyond 12 months.
- Unexplained paraesthesia in the arm.

Common ways to assess progress in LE rehabilitation
The Patient-Rated Tennis Elbow Evaluation (PRTEE) is a quick and inexpensive questionnaire to assess subjective outcomes of pain and function.
Pain free grip (PFG) measured using a dynamometer is a simple objective marker.
