Background: The aim of the present study was to enhance a topical delivery of hirsutenone (HST), a naturally occuring immunomodulator, employing Tat peptide-admixed elastic liposomes (EL/T).

Methods: HST-loaded EL, consisting of phosphatidylcholine and Tween 80 (85:15 w/w%), were prepared using thin film hydration method. By adding Tat peptide to EL (0.16 w/w%), EL/T were formulated. The in vitro skin permeation of HST was examined using a Franz diffusion cell mounted with depilated mouse skin. Lesions for atopic dermatitis (AD) were induced by a topical application of diphenylcyclopropenone to NC/Nga mice. Therapeutic improvements of AD were evaluated by clinical skin severity scores. Immunological analyses on inducible nitric oxide synthase and cyclooxygenase-2 levels in the skin and interleukin (IL)-4, IL-13, immunoglobulin E, and eosinophil levels in the blood were also performed.

Results: EL systems were superior to conventional cream, revealing greater flux values in a permeation study. The addition of Tat peptide further increased the skin permeation of HST. In an efficacy study with AD-induced NC/Nga mice, an HST-containing EL/T formulation brought a significant improvement in both skin severity score and immune-related responses for the levels of nitric oxide synthase, cyclooxygenase-2, IL-4, IL-13, immunoglobulin E, and eosinophils.

Conclusion: A novel EL/T formulation was successfully developed for topical delivery of HST to treat AD.

Keywords: hirsutenone, elastic liposomes, atopic dermatitis, NC/Nga mice, Tat peptide

Introduction
Patients with atopic dermatitis (AD), a chronically relapsing inflammatory skin disease, suffer from allergic symptoms such as redness, flaking, and itching.¹ The causes of AD are not completely understood, but complex inflammatory immune dysregulation and susceptible responses to environmental allergens are believed to be involved.² AD is characterized by type 2 helper T cell (Th2)-dominated immunity that leads to elevated levels of serum immunoglobulin E (IgE) and peripheral eosinophils.² ³ It is also indicated by increased inflammatory enzymes including inducible nitric oxide synthase (iNOS) and cyclooxygenase-2 (COX-2) in the skin. Topical corticosteroids as immunosuppressors have been used for over 50 years as first-line therapy for AD, but their side effects, including skin atrophy and striae, are major obstacles for long-term application.⁴ Alternatively, many potential compounds originating from natural sources such as olive oil, omega oils, royal jelly, and magnolol have been widely investigated to develop a natural remedy for AD.⁵ ⁸

Hirsutenone (HST), 1,7-bis-(3,4-dihydroxyphenyl)-4-heptene-3-one, is one of the major diarylheptanoids isolated from the bark of Alnus japonica.⁹ Hirsutenone inhibits...
12-O-tetradecanoylphorbol-13-acetate (TPA)-induced COX-2 expression and the synthesis of prostaglandin E₂ in human mammary epithelial MCF 10A cell lines. A recent study revealed that HST reduced the production of cytokine mRNAs such as interleukin (IL)-2, 4, 5, 13, and interferon-γ after T-cell receptor stimulation and, remarkably, suppressed the degranulation of mast cells, indicating the feasibility of HST as a new topical drug candidate for AD therapy. By virtue of its lipophilic nature, HST could be actively translocated into cells. However, because of the water-insoluble properties of HST, solubilization and incorporation of the drug are necessary for topical formulation development. In addition, a penetration-enhancing system is required to achieve therapeutic concentrations to deeper skin layers of the epidermis and/or dermis. Several methods to enhance skin delivery have been explored by employing chemical enhancers, creams, vesicular carriers, ultrasound aids, and the use of microneedles. It was found that elastic liposomes (EL), a phospholipid vesicular system containing edge activators, were very effective in enhancing the dermal and/or transdermal deliveries of both lipophilic and hydrophilic molecules. Compared with the conventional liposomes, EL are able to respond to an external stress by rapid shape transformation and can penetrate the skin efficiently in terms of quantity and depth. Researchers have proposed that these liposomal vesicles could improve the skin delivery of drugs by one of the following mechanisms: intact vesicular skin penetration, a penetration enhancing effect, or penetration of liposomes through the transappendageal route. Another pharmaceutical approach to enhance skin delivery is to employ cell-penetrating peptides. Some experiments have demonstrated that cell-penetrating peptides including YARA, WLR, R9, and Tat (Trans-activating transcriptional activator) peptides were useful not only for intracellular delivery but also for promoting the skin penetration of molecules in mice. A recent study showed that Tat peptide facilitates the translocation of drugs into immune cells in the skin.

Therefore, a novel Tat peptide-admixed EL (EL/T) containing HST was developed. The in vitro skin permeation properties and in vivo therapeutic efficacy of this formulation were then compared with other formulations of either the cream type or an EL system. Therapeutic improvements of AD in NC/Nga mice were evaluated by clinical skin severity scores. The immunological analyses of suppression levels for iNOS, COX-2, IL-4, IL-13, IgE, and eosinophil were also conducted.

**Materials and methods**

**Animals**

Male 5-week-old ICR mice and female 5-week-old NC/Nga mice were purchased from Orient Bio (Kyungki-Do, Korea) and Charles River (Yokohama, Japan), respectively. They were maintained for 2 weeks before the start of the experiments and were housed in an air-conditioned animal room with a 12-hour light–dark cycle (08:00–20:00 hours light, 20:00–08:00 hours dark) at a controlled temperature of 23°C ± 2°C and humidity of 50% ± 10%. Mice were provided with a laboratory diet and water ad libitum. All animal experiments were performed in accordance with the National Institutes of Health (NIH) Principles of Laboratory Animal Care guidelines (NIH publication No. 85-23, revised 1996) and were approved by the Institutional Animal Care and Use Committee of Chung-Ang University in Seoul, South Korea.

**Chemicals and reagents**

Hirsutenone (purity >95% by high-performance liquid chromatography [HPLC]) was provided from Chung-Ang University Pharmacognosy Laboratory (Seoul, South Korea). Soybean phosphatidylcholine (PC), cholesterol, Tween 80, phosphate-buffered saline (PBS) tablets, butylated hydroxytoluene (BHT), and N,N-diethylcarbamylamine (DENA) were purchased from Sigma Aldrich (St Louis, MO). Tat peptide (Arg-Lys-Lys-Arg-Gln-Arg-Arg-Arg, 9 mer) was synthesized from Peptron Co (Taejun, South Korea). Polyglyceryl-3-methylglucose distearate, stearic acid, cetly alcohol, mineral oil, and glycerin used for cream preparation were kindly provided by LG Life Science Ltd (Seoul, South Korea). Sodium carboxymethylcellulose was purchased from Duksan Pure Chemical Co (Kyungkido, South Korea). All other chemicals and reagents were purchased from commercial sources and were of analytical grade. Doubly distilled water was used for all experiments.

**Preparation of topical formulations**

**Preparation of EL formulations**

HST-loaded EL were prepared using a previously published thin-film hydration method. Briefly, PC and Tween 80 (85:15 w/w%) were dissolved in chloroform and methanol (1:1) in a round-bottom flask. After dissolving HST, the organic solvent was removed by rotary vacuum evaporation above the lipid transition temperature and solvent traces were removed under nitrogen gas. The lipid film was then hydrated with distilled water containing an antioxidant (BHT 0.005 w/v%) to prevent drug oxidation and
then sonicated in a bath sonicator (model 2210, Branson Ultrasonics Co, Danbury, CT) for 20 minutes. Tat-admixed EL (EL/T) were formulated by adding Tat peptide to EL at a concentration of 0.16 (w/w%), equivalent to the peptide to lipid molar ratio of 0.1:100. The final lipid concentration in all vesicular formulations was 13 mg/mL, and the drug concentration was 1.0 w/w%. A thickening agent, sodium carboxymethylcellulose, was added to both EL formulations at a concentration of 0.5 w/w% to improve the application of formulations to the postaxial back of the mouse.

Preparation of cream formulations
A conventional oil-in-water type cream (CC) containing 1.0 w/w% HST was prepared as follows. Water-insoluble HST was dissolved in an oil phase consisting of mineral oil (7%), stearic acid (5%), cetyl alcohol (2%), and BHT (0.005%), with polyglyceryl-3-methylglucose distearate (3%) used as an emulsifier. The aqueous phase consisted of glycerin (10%) and distilled water. The oil phase was added to the aqueous phase and then homogenized for 10 minutes, degassed, and cooled under vacuum. Tat-admixed conventional cream (CC/T) was prepared by mixing Tat peptide into CC at a concentration of 0.16 w/w% and rehomogenizing for 3 minutes. Both cream formulations were then stored for about 24 hours before subjected to evaluation.

Physical characterization of EL formulations
Size and zeta potential
Liposomal vesicles were diluted with an appropriate volume of water and were examined for size distribution and zeta potential using a dynamic light scattering particle size analyzer (Zetasizer Nano-ZS; Malvern Instruments, Worcestershire, UK) with a 50 mV laser at a scattering angle of 90°. All measurements were carried out under ambient conditions and in triplicate.

Loading efficiency
Unencapsulated drug was separated from the liposomes by centrifugation at 15,000 rpm for 10 minutes.24 The supernatant was analyzed for HST by HPLC. The entrapment efficiency of the liposomes was calculated by \( [(T - C)/T] \times 100 \), where \( T \) is the total amount of drug initially added, and \( C \) is the amount of drug detected in the supernatant.24

Elasticity of the vesicle membrane
The vesicle suspension was driven through a microporous filter by an external pressure of 2.5 bars.25 The size of the vesicles was monitored using dynamic light scattering measurement before and after filtration. The elasticities of the vesicle membranes were calculated using the previously reported formula: \( D = J \times (r_v/r_p)^2 \), where \( D \) is the deformability index of the vesicle membrane, \( J \) is the amount of vesicle suspension extruded for 5 min, \( r_v \) is the size of the vesicle after extrusion, and \( r_p \) is the pore size of the barrier.26

In vitro skin permeation study
Solubilization of HST for sink conditions
To maintain the sink conditions in the receptor compartment for HST, DENA was selected as a hydrotropic agent for solubilization of the hydrophobic drug.27 An excess amount of HST was added to PBS containing various concentrations of DENA and then vortexed. The mixture was shaken intermittently at ambient temperature for 24 hours to reach equilibrium. The supersaturated sample was centrifuged at 12,000 rpm for 10 minutes to separate the undissolved HST. The supernatant was then filtered through a 0.45 µm membrane filter (Whatman, Piscataway, NJ) and diluted with methanol for the HST assay by HPLC.

Skin permeation of HST
An in vitro permeation study was conducted with vertical Franz diffusion cells as previously described.18,28 Skin tissues were obtained from hairy ICR mice, from whom the dorsal hair of the mouse skin was carefully removed using electric clippers and rinsed with phosphate buffer. A circular piece of dorsal skin was then carefully mounted onto the receiver compartment of the diffusion cells with the stratum corneum facing toward the donor compartment. The receptor compartment was filled with 10 mM PBS (pH 7.4) solution containing 1.5 M DENA and was maintained at 32°C. Each formulation containing the equivalent amount of HST (5.0 mg) was applied to the skin surface, which had an available diffusion area of 1.76 cm². The aliquots (0.5 mL) were withdrawn at predetermined time intervals and analyzed by HPLC. The cumulative amount of drug permeated per unit area was plotted as a function of time. The steady-state permeation rate (\( J_s \)) and lag time (\( T_l \), hours) were calculated from the slope and X-intercept of the linear portion, respectively.

HST assay by HPLC
The quantitative determination of HST was performed by HPLC using acetonitrile-0.3% acetic acid in water (25:75) as a mobile phase at a flow rate of 1 mL/minute. The HPLC system consisted of a pump (L-2130), a UV detector (L-2400), a data station (LaChrom Elite, Hitachi, Japan),
and a 15 cm C18 column (Shiseido, Tokyo, Japan). The column eluant was monitored at 220 nm, and the HST peak was separated at a retention time of 12.0 minutes.

In vivo efficacy and immune-related responses

Induction of AD in mice and the topical application of HST

AD-like lesions were induced by a topical application of diphenylcyclopropenone (DPCP), a well-known contact allergen, to NC/Nga mice as previously described.29 The mouse skin was stimulated for 10 weeks by 0.1% DPCP solution under ambient conditions. AD was characterized by itching, erythema, and hemorrhage, followed by edematous superficial erosion, deep excoriation, scaling, and dryness of the skin.30 For topical application, regrown hairs on the postaxial backs of the mice were removed a day before the experiment. The mice were treated daily for 4 weeks with drug-free CC base alone (control) or drug-containing topical formulations of CC/T and EL/T.

Clinical observation of skin severity

The clinical severity of dermatitis was assessed in a blinded fashion using a previously described method.8,29 A total score for skin severity was defined as the sum of the individual scores, graded as 0 (no lesion), 1 (mild lesion), 2 (moderate lesion), and 3 (severe lesion), for each sign and symptom, such as erythema, edema, oozing or crust, excoriation, lichenification, and dryness.

Measurement of iNOS and COX-2 levels in skin

Mice were sacrificed at 4 weeks after HST treatment. An area of approximately 1.5 × 1.5 cm² was excised, and the subcutaneous fat and blood vessels were carefully dissected away. Expression levels of iNOS and COX-2 in the skin were measured by Western blotting.31 Skin tissues were lysed in a buffer containing 50 mM tris(hydroxymethyl)amino methane, 150 mM sodium chloride, 0.02% sodium azide, 100 μg/mL phenylmethanesulfonyl fluoride, 1% Triton X100, and 1 μg/mL aprotinin. After centrifugation, the supernatant was loaded onto a 15% sodium dodecyl sulfate polyacrylamide gel and electrophoresed. For iNOS and COX-2 detections, the electrophoretically resolved proteins were transferred onto nitrocellulose membranes (Osmonics, Milwaukee, WI). The membrane was incubated with anti-iNOS and COX-2 polyclonal antibodies (1:1000 in 5% bovine serum albumin [Chemicon, Temecula, CA]) and then washed three times with a Triton X100-containing PBS solution. Relative protein levels were measured using scanning densitometry of the band intensities in the immunoblots after visualization of protein with an enhanced chemiluminescence detection kit (ECL Advance Western Blotting Detection Kit; Amersham Pharmacia Biotech, UK).

Measurement of IL-4, IL-13, IgE, and eosinophil levels in blood

The amounts of IL-4, IL-13, IgE, and eosinophil in treated mouse blood were quantified according to a previously described method.32 Blood was collected from the retro-orbital plexus of mice under ether anesthesia. Serum was obtained by centrifugation of whole blood at 12,000 rpm and was stored at −20°C until use. The levels of IL-4 and IL-13 were measured using a mouse IL-4 ELISA kit and a mouse IL-13 ELISA kit (R&D Systems, Minneapolis, MN). The amount of total IgE in the serum was determined using a mouse IgE ELISA kit. An eosinophil count was conducted on 30 μL of capillary blood diluted sixfold with saline. Microscopic differential counts were performed on Wright–Giemsa-stained blood smears. Eosinophil counts were calculated from the differential counts.

Statistical analysis

All data are expressed as mean ± standard deviation. Statistical significance was checked by t-test and was considered to be significant at P < 0.05, unless otherwise indicated.

Results and discussion

Characteristics of topical formulations

EL formulations were characterized by vesicular size, zeta potential, loading efficiency, and deformability index. Vesicular size was measured on average at 130–150 nm, which is considered as an ideal size for skin delivery.33 Surface charges in the EL were measured at about −30 mV but were neutralized by the addition of Tat peptide to about −10 mV due to electrostatic adhesion of the cationic peptide to the vesicular surface. EL formulations showed a high loading efficiency of HST over 70%. HST was efficiently encapsulated into the liposome due to its lipophilicity. In comparison, liposomal encapsulation of oregonin, a hydrophilic diarylheptanoid as a glycoside form, has been shown to be markedly lower than that of HST.34 The deformability index of EL, a crucial feature of elastic liposomes for skin penetration enhancement, was observed at about 60, which is a three- to fourfold greater value than that of conventional liposomes.14,34 The incorporation of an edge activator, Tween 80, destabilized the lipid bilayers, thereby increasing the deformability of the vesicles.35 The stress-dependent adaptability of EL imparts an exclusive
ability to pass through the skin barrier with ease, which in turn provides an adjuvant effect for HST permeation. Conventional oil-in-water type cream formulations were prepared successfully and appeared as white, opaque, homogeneous semifluids with no bleeding or phase separation. HST was solubilized in the oil phase, and no drug crystals were observed. Under the presence of the antioxidant BHT (0.005%), the drug contents in all formulations were maintained at over 98% during the experimental period.

Sink conditions for skin permeation study
Although physiological saline was potentially the most appropriate receptor phase, an appropriate solubilizing agent was required to provide a sufficient solubility for HST and to maintain the sink conditions during the permeation studies. The aqueous solubility of HST was increased by several orders of magnitude in the presence of DENA, a novel hydrotropic agent (Figure 1). The increased solubilization might be attributed to the complexation of DENA with the drug molecule, alterations in the nature of water as a solvent, and self-associations in aqueous solution at high concentration of the hydrotropic agent (>1 M). In particular, a medium with 1.5 M DENA provided about 6 mg/mL of HST solubility. This equilibrium solubility guarantees the sink conditions for HST, because the total amount of HST in the donor phase was 5 mg, and the volume of the receptor phase was 11 mL in the Franz diffusion cell.

Skin permeation profiles of HST
The in vitro permeation profiles of HST in various topical formulations, including CC, CC/T, EL, and EL/T, are shown in Figure 2. Permeation of HST in conventional creams was significantly lower than those of the liposomal formulations. The slope of the EL/T formulation was much steeper than those of the other formulations. The order of HST penetration at 24 hours was as follows: EL/T > EL > CC/T > CC. The skin permeation parameters of HST from liposomal and non-liposomal formulations are summarized in Table 1. Compared with cream formulations, liposomal formulations revealed greater values in flux and cumulative amount permeated at 24 hours. However, incorporation of the drug into liposomes resulted in skin permeation time lag because of the required time for HST-containing liposomal nanovesicles to migrate from the gel matrix of the vehicle. In particular, EL/T formulation significantly increased the amounts of HST permeated (%): 1.7-fold versus EL, 2.7-fold versus CC/T, and 4.1-fold versus CC. It was determined that EL systems were superior to cream formulations and that the addition Tat peptide even further improved topical delivery of HST.

In looking further into the details of flux values for different formulations, formulation effects on the skin permeation of HST for two variables were noticed: EL formulation and

Tat peptide addition (Figure 3). The enhancement ratio was expressed as a relative ratio of the flux values. EL and EL/T showed enhancement ratios of 2.7 and 3.1 versus CC and CC/T, respectively. The high, stress-dependent transformability of EL enabled them to travel between the cells in the stratum corneum, which effectively allows them to pass through the intact skin spontaneously under the influence of the naturally occurring transcutaneous hydration gradient. A previous study has shown that EL rapidly enters the deeper layers of the stratum corneum and can reach layers almost as deep as the stratum corneum-viable epidermal junction.15,38 However, the addition of Tat peptide further intensified the skin penetration-enhancing capacity of EL. EL/T exhibited an enhancement ratio of 1.7 versus that of EL, which followed a similar trend to the cream formulations. This result is consistent with an earlier report that stated that the noncovalent WLR fragment, one of the penetrating peptides, was twice as effective in promoting the penetration of macromolecules into the skin.19 It is also supported by an earlier report stating that several penetrating peptides are able to interact with lipids in the stratum corneum and enter into a layer of cells via a macropinocytosis mechanism, forming a gradient from the outer to the inner cell layers, thus facilitating the delivery of drug.39

**In vivo therapeutic efficacy for skin severity**

To evaluate the therapeutic efficiency of HST-loaded EL/T and CC/T formulations for AD severity in vivo, AD-like lesions were artificially induced in NC/Nga mice. Mice with AD-like lesions manifested with severe pruritis, dryness, and eczema, showing no significant differences in severity level between mice. AD-like lesions on the dorsal skin in the control group presented as a reddish-colored wound and dried skin even after 4 weeks. Compared with the normal group, the HST-treated groups showed considerable reductions in these symptoms, demonstrating complete recovery within 4 weeks following treatment (Figure 4). Evaluation of AD scoring (SCORing Atopic Dermatitis) for skin severity (Figure 5) showed that both EL/T and CC/T formulations started to show significantly different improvements within a week, and that the values continued to reduce gradually for up to 4 weeks. The EL/T-treated group revealed the best result with complete recovery within 2 weeks following topical application, a significant difference ($P < 0.05$) from that of the CC/T treatment. The superiority of the EL/T formulation correlated very well with the in vitro skin permeation results. This trend in formulation differences was maintained for 3 weeks after treatment, even though there was a small decrease in score values. However, at 4 weeks after treatment, there were no significant differences between the EL/T- and CC/T-treated groups. It is therefore concluded that the EL/T formulation brought about a rapid and profound improvement as an AD therapy.

Suppression of iNOS and COX-2 levels in skin
Diarylheptanoids including HST have been shown to promote antioxidant effects through scavenging actions on superoxides and 1,1-diphenyl-2-picrylhydrazyl radicals. These compounds prevent the expressions of iNOS and COX-2 in RAW264.7 macrophages in a dose-dependent manner. Both HST-treated groups resulted in marked declines in both iNOS and COX-2 expression levels (Figure 6), which were significantly different \( (P < 0.05) \) from those of the control. Although a more than 50% reduction in expression levels was obtained using the CC/T treatment, the EL/T treatment decreased the levels even further to about 30%, revealing significant differences between the two treatment groups. In accordance with the clinical observations of skin severity, the entrapment of the drug in an EL/T system facilitated the transfer of HST to skin and thereby increased the anti-inflammatory activity of the drug.

Suppression of IL-4, IL-13, IgE and eosinophil levels in blood
In the present study, repeated treatment with DPCP in NC/Nga mice triggered IgE and eosinophil hyperproduction with upregulation of IL-4 and IL-13. All immune response levels were greatly elevated in the control group, in which the elevation remained constant even after 4 weeks of treatment with drug-free cream base (Figure 7). Studies of NC/Nga mice with AD symptoms have also demonstrated the elevation of immune responses, including IL-4, IL-13, IgE, and eosinophil levels. The increased serum IgE level would be driven from the Th1/Th2 imbalance skewed to Th2, in which Th2 cytokines such as IL-4 and IL-13 play key roles in the hyperproduction of IgE. In addition, leukotrienes generated by eosinophils amplify inflammatory cascades by acting as chemotactic factors or by triggering the release of cytotoxic proteins. Meanwhile, HST treatment with CC/T or EL/T formulation brought remarkable and significant reductions in all levels to less than half of that of the control \( (P < 0.05) \), revealing the effectiveness of HST for AD therapy. However, unexpectedly, there were no significant differences between the two treatment groups in the suppression levels for IL-4, IL-13, IgE, or eosinophils. These results might be due to the fact that expression levels of these parameters were mostly normalized in NC/Nga mice after 4 weeks of HST application regardless of its formulation.
Conclusion
A major obstacle to achieving therapeutic effectiveness is delivery of the pharmacologically active agent to its site of action. The results of this study show that elastic liposomal formulations can be advantageous for the topical delivery of HST, a naturally occurring lipophilic immunomodulator, in vitro skin permeation and in vivo therapeutic efficacy. Therefore, the HST-loaded EL/T formulation developed in this study can be used to treat AD as an alternative to steroid therapy, which is very limited for long-term application due to the severe side effects.
