Background: Genus Enterobacter includes important opportunistic nosocomial pathogens that could infect complex wounds. The presence of antibiotic resistance genes in these microorganisms represents a challenging clinical problem in the treatment of these wounds. In the authors’ screening of antibiotic-resistant bacteria from complex wounds, an Enterobacter species was isolated that harbors antibiotic-resistant plasmids conferring resistance to Escherichia coli. The aim of this study was to identify the resistance genes carried by one of these plasmids.

Methods: The plasmids from the Enterobacter isolate were propagated in E. coli and one of the plasmids, designated as pR23, was sequenced by the Sanger method using fluorescent dye-terminator chemistry on a genetic analyzer. The assembled sequence was annotated by search of the GenBank database.

Results: Plasmid pR23 is composed of the transposon Tn1331 and a backbone plasmid that is identical to the plasmid pPIGDM1 from Enterobacter agglomerans. The multidrug-resistance transposon Tn1331, which confers resistance to aminoglycoside and beta lactam antibiotics, has been previously isolated only from Klebsiella. The Enterobacter plasmid pPIGDM1, which carries a CoIE1-like origin of replication and has no apparent selective marker, appears to provide a backbone for propagation of Tn1331 in Enterobacter. The recognition sequence of Tn1331 transposase for insertion into pPIGDM1 is the pentanucleotide TATTA, which occurs only once throughout the length of this plasmid.

Conclusion: Transposition of Tn1331 into the Enterobacter plasmid pPIGDM1 enables this transposon to propagate in this Enterobacter. Since Tn1331 was previously isolated only from Klebsiella, this report suggests horizontal transfer of this transposon between the two bacterial genera.

Keywords: transposon Tn1331, Enterobacter, wound infection

Introduction

Bacteria from the genus Enterobacter, particularly Enterobacter cloacae, Enterobacter agglomerans, and Enterobacter aerogenes, are important opportunistic nosocomial pathogens responsible for skin, soft tissue, urinary tract, and gastrointestinal tract infections.1-5 These microorganisms also infect various types of complex wounds and represent a challenging clinical problem in their treatment.6,7 Consequently, the emergence of multidrug resistant strains of Enterobacter, thought to be correlated with the ubiquitous and empirical use of antibiotics,8,9 is of great concern to clinicians treating wound infections.

Bacteria acquire drug-resistant phenotypes through either spontaneous mutations or acquisition of resistance genes from the environment. Horizontal gene transfer (HGT) is
one of the most effective mechanisms for a bacterium to gain new functionally relevant genes from other microorganisms in their environment.9,10 Mobile genetic elements such as transposons carrying antibiotic-resistance genes can be transmitted by HGT and, as a result, play a significant role in the transfer and spread of antibiotic resistance in bacterial populations. To date, several transposons have been identified in pathogenic *E. cloacae* that carry resistance markers to a wide spectrum of antibiotics. These include Tn2101, Tn402 derivatives, often in association with Tn21; 12–14 Tn7,15 and Tn6005.16 Some of these transposons, like Tn402 derivatives, have also been identified in *Pseudomonas*, indicating exchange of antibiotic-resistance genes between *Enterobacter* and *Pseudomonas* species, possibly by HGT.14

Previously, the authors have reported isolation of a multiple antibiotic-resistant *Enterobacter* species from a clinical wound sample that was closely related to *E. cloacae* and was designated *Enterobacter* sp W001.17 This bacterium carries plasmids that could confer kanamycin and ampicillin resistance to an antibiotic-sensitive laboratory strain of *Escherichia coli*. In the present study, the sequence and organization of one these plasmids, which suggests direct or indirect horizontal transfer of a transposon between *Klebsiella* and *Enterobacter*, is reported.

### Materials and methods

#### Bacterial strains and cultivation

The plasmid analyzed in this study originated from a bacterial isolate from a clinical wound sample, as previously described.17 Briefly, the clinical sample was screened for presence of ampicillin- and kanamycin-resistant bacteria by antibiotic-selective agar method. One of the resistant colonies was subjected to 16S rDNA sequence analysis and biochemical assays using a Phoenix Automated Microbiology System (BD, Franklin Lakes, NJ). This bacterium was determined to be 99% similar to *E. cloacae* by both 16S rDNA and Phoenix analysis and was designated *Enterobacter* sp W001. *Enterobacter* sp W001 was maintained on Tryptic Soy Agar and grown in Tryptic Soy Broth (both Thermo Fisher Scientific, Rockford, IL) for plasmid extraction using QIAprep Spin MiniPrep Kit (Qiagen, Valencia, CA).

Plasmid extracted from *Enterobacter* sp W001 was transformed into the commercially available competent *E. coli* TOP10 cells (Invitrogen, Carlsbad, CA) according to the manufacturer’s instructions. The transformed cells were selected on kanamycin- and ampicillin-selective agar plates. A resistant colony from the transformants was selected for plasmid extraction and analysis. Plasmid extracted from this colony was designated pR23.

#### Cloning, sequencing, and bioinformatics analysis

To clone and sequence the plasmid pR23, it was double digested with restriction enzymes HindIII/PstI or BamHI/PstI (New England Biolabs, Ipswich, MA). The fragments were cloned into a pUC19 plasmid, which was either singly digested with PstI, HindIII, or BamHI, or double digested with PstI/HindIII or PstI/BamHI. The recombinant plasmids were propagated in *E. coli* TOP10 cells and purified using QIAprep Spin MiniPrep Kit. Plasmids were sequenced in the authors’ laboratory by the Sanger method using M13 forward and reverse primers and fluorescent dye-terminator chemistry on an ABI 3100-Avant Genetic Analyzer (Life Technologies Corp, Carlsbad, CA). To complete the sequence of large fragments, primers were designed based on the first round of sequencing and used for DNA walking of the larger fragments. In those instances where DNA walking of the large fragments was difficult due to presence of repeats in DNA sequence, the primers were used in polymerase chain reaction amplification of the interior sections, which we cloned the amplicons into TOPO TA Cloning® (Invitrogen) according to the manufacturer’s instructions and sequenced. Sequencing reads were assembled into contigs, then assembled into the final complete plasmid sequence using Geneious Pro (v 5.1; Biomatters Ltd, Auckland, New Zealand). The accuracy of the assembly was confirmed by resequencing different parts of the plasmid after amplification by polymerase chain reaction using primers based on the assembled sequence. The plasmid sequence was annotated by a BLAST search of the GenBank® database according to the highest similarity scores. The sequence of the pR23 plasmid has been submitted to the GenBank and the Accession number is JF703130.

#### Results and discussion

**Plasmid pR23 harbors transposon Tn1331**

The plasmid originating from the clinical isolate *Enterobacter* sp W001 and carrying antibiotic-resistance genes was designated as pR23. As shown in Figure 1, pR23 is composed of a transposon that carries antibiotic-resistance genes and a backbone plasmid. The transposon is 100% identical to the multidrug-resistance transposon Tn1331 from plasmid pJHCMW1 (Accession number NC_003486), which was isolated from a *Klebsiella pneumoniae* strain and confers resistance to aminoglycoside and beta lactam antibiotics.19
Tn1331 consists of a Tn3 transposon and two gene cassettes carrying three antibiotic-resistance genes. One of the cassettes carries the aminoglycoside 6′-N-acetyltransferase type Ib (aac(6′)-Ib) gene that confers resistance to aminoglycosides including amikacin and kanamycin. The other cassette contains the streptomycin 3′-adenyltransferase (ant(3′)-Ia) and oxacillinase/carbapenemases beta-lactamase (blaOXA-9) genes that code for resistance to streptomycin and beta lactams, respectively. The two gene cassettes have integrated between the resolvase (tnpR)-resistance and ampicillin-resistance (blaTEM-1b) genes of transposon Tn3 by a mechanism that has resulted in partial duplication of the resolvase gene (tnpR').

Although Tn1331-related sequences and partial components have also been detected in Serratia marcescens, Salmonella serovars, Pseudomonas putida, and Proteus mirabilis,20-24 this transposon and its cluster of antibiotic-resistant genes – in its entirety – has been previously isolated only from K. pneumoniae clinical isolates25,26 (also refer to NCBI Accession number NC_009650 and GU553923).

To the best of the authors’ knowledge, the present study is the first report of Tn1331 association with an Enterobacter species.

Genetic background for Tn1331 on pR23

The second major feature of the plasmid pR23 is the genetic context into which Tn1331 has transposed. The sequence of this backbone is 100% identical to the plasmid pPIGDM1 (Accession number AF014880) from an E. agglomerans originally isolated from a kitchen sink.27 This plasmid carries a CoIE1-like origin of replication, and the rom gene, which is responsible for controlling the copy number of the

Figure 1 Possible mechanism for generation of plasmid R23. Transposon Tn1331 insertion into pPIGDM1 at the insertion site TATTA could lead to generation of pR23 plasmid. Two direct repeats of pentanucleotide TATTA flank inverted repeats (not shown) at the ends of Tn1331 transposon in pR23. Enterobacter plasmid pPIGDM1 carries an origin of replication (rep origin) in enterobacteria and the RNA one modulator (rom) gene, which helps maintain a low plasmid copy number. Tn1331 consists of genes coding for transposase (tnpA), resolvase (tnpR), aminoglycoside 6′-N-acetyltransferase type Ib (aac(6′)-Ib), Aminoglycoside (3′) adenylyltransferase (ant(3′)-Ia), oxacillinase-carbapenemases beta-lactamase (blaOXA-9), partial coding sequence of resolvase (tnpR'), and TEM beta-lactamase (blaTEM-1b). The Accession numbers for the coded proteins are TnpA: NP_608305.1, TnpR: NP_608306.1, AAC(6′)-Ib: NP_608307.1, ANT(3′)-Ia: NP_608308.1, OXA-9: NP_608309.2, and Bla-TEM-1b: NP_608310.1.
plasmid. Another plasmid, pAH2504, which is 99% identical to pPIGDM1, has also been isolated from Aeromonas hydrophila (Accession number DQ389104), suggesting that pPIGDM1 may be harbored by bacterial species from different genera. Plasmids pPIGDM1 and pAH2504, which are small in size, have a low copy number, and no apparent selective markers, are examples of cryptic plasmids that may circulate within different bacteria and serve as a natural backbone plasmid for mobile genetic elements.

The recognition sequence of Tn1331 transposase for insertion into pPIGDM1 was identified as direct repeats of the pentanucleotide TATTA, which flank the inverted repeats at the ends of Tn1331 (Figure 1). This sequence occurs only once throughout the length of the plasmid. The recognition site for Tn1331 transposition appears to be adenine/thymine rich with a frequency of 60%–100%. Transposition sites of Tn1331 into plasmids from K. pneumoniae isolates are present in multiple locations in those plasmids (Table 1). These recognition sequences are also present many times across the length of pPIGDM1, and could represent potential sites for Tn1331 transposition.

Transposons appear to have played an important role in the emergence of antibiotic resistance in members of genus Enterobacter. The first report of a transposon carrying antibiotic-resistance genes in an Enterobacter species was published in 1982.11 A subsequent study has provided strong evidence for association of transposons with antibiotic resistance genes in Enterobacter.25 The present study adds Tn1331 transposon to the list of mobile genetic elements that could contribute to spread of antibiotic-resistance genes in Enterobacter.

In summary, this report suggests transposition of Tn1331 into a new genetic background that allows propagation of its associated antibiotic-resistance genes in a genus other than Klebsiella. The plasmid pPIGDM1 from E. agglomerans, for which no functional relevance had previously been defined, appears to serve as a backbone to facilitate propagation of Tn1331 in an Enterobacter species, perhaps after horizontal transfer of this transposon. Given that clinically important members of Enterobacter are already highly resistant to antibiotics, appearance of new combination of antibiotic-resistance genes and their propagation in these microorganisms is alarming and may further complicate management of complex wound infections.
