Introduction

Fibroadenoma of the breast is relatively frequent. Women can present with fibroadenoma at any age, but the peak incidence is in the second and third decades of life. Fibroadenoma is the most common benign breast tumor in adolescent girls and young women.1 Growth of fibroadenoma is stimulated by estrogen, progesterone, pregnancy, and lactation,2,3 often presents as a palpable mass measuring up to 3 cm, and may undergo atrophic changes in menopause.

Fibroadenoma is a biphasic tumor composed of a stromal and an epithelial component. Although, fibroadenoma is generally considered benign, there is evidence for an association with an increased risk of invasive breast cancer.1 Furthermore, progression of the epithelial component to carcinoma in situ and invasive carcinoma has been documented in the literature.5-8 Malignant transformation from fibroadenoma to cancer is rare. Moreover, the risk of developing breast cancer was found to be higher in patients with complex fibroadenoma.5 The mean age reported for patients with carcinoma arising in fibroadenoma is in the fifth decade, almost 20 years older than the peak age of women diagnosed with simple fibroadenoma. Cheatle and Culter were the first to describe a carcinoma arising in a fibroadenoma.

Since there are no definite clinical or radiological criteria for diagnosing carcinoma arising in a fibroadenoma, histopathological examination should be performed routinely to rule out malignancy in cases of nonsimple fibroadenoma.

Case presentation

A 69-year-old woman having one first-degree family member with breast cancer presented to the breast imaging unit for screening mammography. She had had screening mammography every 2 years since 1997, with multiple bilateral benign breast masses detected. In 2011, one of the masses in the left breast changed in diameter from 3 cm on mammography done in February 2010 (Figure 3) to 5 cm diameter in mammography done in May 2011 (Figure 2). Ultrasonography revealed a well-circumscribed homogeneous hypoechoic mass 5 cm in diameter (Figure 1). An ultrasound-guided
Ultrasonography revealed a well-circumscribed homogeneous hypoechoic mass 5 cm in diameter.

Mammography in May 2011 revealed well-defined, rounded, and oval masses, some with coarse calcifications and the largest being 5 cm in diameter (white arrow).

Mammography in February 2010 revealed well-defined, rounded and oval masses, some with coarse calcifications the largest being 3 cm in diameter (white arrow).

Within the typical fibroadenoma, irregular groups of invasive carcinoma cells are seen in the stroma (arrows). Hematoxylin and eosin (HE) ×50.

Nests of invasive carcinoma (arrow). Hematoxylin and eosin (HE) ×100.

Myoepithelial cells are absent in invasive carcinoma (black arrow), and myoepithelial cells are preserved in fibroadenoma structures (white arrow). Calponin immunostain ×100.

Discussion

Fibroadenomas are common benign lesions of the breast that usually present as a single breast mass in young women. Simple fibroadenomas have a reported incidence of 7%–13% in women from adolescence through the mid 20s who present to specialty clinics. The prevalence of simple fibroadenomas decreases with age. A review of the literature shows that fibroadenomas are associated with a lower incidence of breast malignancy compared to other breast lesions. The most common malignant transformation is ductal carcinoma in situ (DCIS), with a reported incidence of 2%–6% in fibroadenomas. Treatment of fibroadenomas is typically conservative, with observation or surgical excision based on the size and symptoms of the mass. The management of fibroadenomas in patients with a history of breast cancer or a family history of breast cancer may require a different approach, with more aggressive management or closer follow-up. The case described above highlights the importance of thorough evaluation and follow-up in patients with fibroadenomas, as well as the potential for malignant transformation of these lesions.
fibroadenomas in this age group in the general population is reported to be 2.2% and is said to decrease with increasing age. The incidence of carcinoma within fibroadenoma is reported to be 0.1%–0.3% in a screened population, with a peak age of occurrence at 42–44 years. Two-thirds of carcinomas within fibroadenoma are lobular and one-third are ductal or mixed ductal and lobular; lobular carcinoma in situ and ductal carcinoma in situ has an approximately equal frequency.

Complex fibroadenomas and proliferative disease adjacent to fibroadenoma are associated with a slight increase in the risk of breast cancer. Invasive ductal carcinoma within fibroadenoma is rare. Although malignant transformation of a fibroadenoma is infrequent, the presence of this tumor in a woman with a positive family history of breast cancer may have greater clinical importance than a fibroadenoma arising in a woman with no additional risk factors. Detection of malignancy developing within a fibroadenoma can be difficult. Clinical and radiological signs may be masked. Physicians should be aware of the potential for progression of breast fibroadenoma, particularly in women with a known BRCA mutation or a strong family history. This case report supports the need for a more aggressive diagnostic approach towards solid benign-appearing breast lesions in women with a strong positive family history of breast and/or ovarian cancer.

Conclusion

Despite the low percentage of carcinoma occurring within fibroadenoma we consider that each lump that changes in diameter or echogenicity should be seriously managed; extirpation and histological examination are recommended. Special caution is warranted in women older than 35 years presenting with a fibroadenoma more than 2 cm in diameter. The possibility of carcinoma originating within fibroadenoma should be considered in cases of lung metastases in women with known fibroadenoma.
