Abstract: Contrast-enhanced magnetic resonance imaging (CE-MRI) is an important clinical tool for diagnosing neurological diseases. The appropriate use of a suitable MRI contrast agent or contrast pharmaceutical is essential for CE-MRI to produce desirable diagnostic images. Currently, there are seven contrast agents (CAs) or pharmaceuticals approved for clinical imaging of the central nervous system (CNS) in the US, Europe, or Japan. All of the clinically approved CAs are water-soluble gadolinium-based contrast agents (GBCAs) which do not penetrate the CNS blood–brain barrier (BBB). These agents are used for imaging CNS areas without a BBB, or various pathologies, such as tumors and infection that break down the BBB and allow CAs to enter into the surrounding parenchyma. Clinically, GBCAs are most useful for detecting primary and secondary cerebral neoplastic lesions. Among these CNS GBCAs, gadobutrol (Gd-BT-DO3A, Gadovist\(^\text{TM}\)) is a neutral, nonionic, macrocyclic compound that showed promising results from clinical trials of CNS imaging. In comparison with other GBCAs, Gd-BT-DO3A has relatively high in vitro kinetic stability and r\(_1\) relaxivity. Gd-BT-DO3A has been recently approved by the US Food and Drug Administration (FDA) in 2011 for CNS imaging. A review of available literature shows that Gd-BT-DO3A exhibits similar safety and clinical efficacy profiles to other GBCAs. Gd-BT-DO3A has the distinguishing feature that it is the only clinical agent commercially available in a formulation of 1.0 M concentration with a relatively higher in vitro r\(_1\) shortening per unit volume than other clinical GBCAs which are only available in 0.5 M concentration. This double concentration of Gd-BT-DO3A may allow a relatively higher concentration of the agent to localize in the CNS and produce a better contrast enhancement at the same clinical dose as other GBCAs. Several recent published multicenter clinical trials appeared to support this potential advantage of Gd-BT-DO3A.

Introduction

Current clinical magnetic resonance imaging (MRI) produces images by measuring the radiofrequency (RF) signals that arise from exposing water protons (\(^1\)H) in living tissues of the patient to a high external magnetic field created by the clinical MRI imagers.\(^1\),\(^2\) Because the magnetic properties of \(^1\)H are sensitive to the local microstructure and tissue composition, detailed anatomical images of high resolution as well as physiological information such as tissue perfusion and blood flow can be quantified by specific MRI measurement. The normal contrast in the clinical MRI images represents the relative difference in signal intensities between two adjacent regions displayed on a gray (or color) scale. The major contributing factors to the signal intensities are the proton longitudinal relaxation time (T\(_1\)) and transverse relaxation time (T\(_2\)). However, there are many pathological conditions...
that do not lead to sufficient MRI signal intensity difference between normal and abnormal tissues because of the intrinsic insensitivity of MRI. In these conditions, the pathology may be detected by introducing exogenous MRI contrast agents (CAs) or contrast pharmaceuticals to locally change the magnetic properties of the diseased tissue. Frequently, the sensitivity and accuracy of clinical MRI in diagnosis of diseases are significantly increased by the utilization of CAs that have been proven to be safe for human use.

MRI plays an important role in the detection, diagnosis, and management of patients with various neurological diseases.3–5 With recent advances in technologies, MRI offers high physiological sensitivity and spatial resolution of the brain.3,7 Some of these capabilities arise from the use of exogenous contrast pharmaceuticals to enhance the contrast between normal and abnormal tissues of the central nervous system (CNS). This contrast-enhanced MRI (CE-MRI) approach improves sensitivity, increasing the detection and delineation of normal and pathological structures in CNS clinical studies. Current clinical CE-MRI of the CNS mainly utilizes CAs that consist of the paramagnetic gadolinium(III) (Gd3+)

biospheres that work as positive CAs by shortening the T1, T2, and T2* relaxation time constants of surrounding water protons to indirectly produce the signal-enhancing effect.8 At normal clinical doses of 0.1–0.2 mmol/kg, the T1 effect tends to dominate. All of the gadolinium-based CAs (GBCAs) are approved for clinical use in humans are nonspecific agents, and their clinical use in CNS imaging is limited by the blood–brain barrier (BBB). There are negative CAs such as superparamagnetic particles/nanoparticles which primarily shorten T1, and T2*, but none of these agents are commercially available for clinical applications for CNS imaging. With a better understanding of the complex contrast enhancement mechanism as well as advances in the field of cellular and molecular imaging, specific tissue/molecular-targeted CAs that can penetrate the BBB and smart-activated/responsive CAs are under active investigations that may lead to more specific targeted imaging in the future.1,2,11–14

The GBCAs for CE-MRI of CNS are primarily focused on detecting CNS lesions.4,5 After intravenous (IV) injection, these low molecular weight gadolinium chelates distribute from the bloodstream into the intravascular, extravascular, and extracellular spaces of the body.3 These agents rapidly equilibrate between intravascular and extravascular spaces with up to 50% first pass extraction fractions. The CNS presents a different environment from the rest of the body because of the existence of the BBB.15,16 The BBB is a network of blood vessels formed by very closely spaced endothelial cells with tight junctions to prevent diffusion of large molecular weight substances into the brain parenchyma. As a result, the use of CAs in the CNS is a challenge but also provides considerably different diagnostic applications, analysis opportunities and physiological inferences.3,16 All current commercially available MRI contrast pharmaceuticals do not cross the intact BBB. An intact BBB prevents the extravasation of these agents from blood vessels into the surrounding brain parenchyma. They are retained intravascularly in the CNS regions with intact BBB. Thus, contrast enhancement with these agents only occurs in the CNS regions without the BBB in healthy adult brains. These regions include the choroid plexus, the pituitary gland and infundibulum, the cavernous sinus, and nasal mucosa. Other possible structures may include vessels, dura mater, and falx cerebri. However, a variety of pathological conditions such as tumors, infarctions, infection, and acute demyelination may cause the BBB to break down and allow these MRI contrast agents to cross into the extracellular space of CNS lesions.

Table 1 shows some examples of the CE-MRI of selected CNS pathologies.15 In these cases of BBB breakdown, small or multiple CNS lesions are more clearly delineated with contrast enhancement. More importantly, contrast enhancement can highlight lesion vasculature, delineate the extent of disease, and confirm the impression of normal or nonmalignant tissues.1,2,5 Thus, CE-MRI of the brain lesions can provide important anatomical information about brain pathology, detailed depiction of

lesion morphology, and the overall extent of disease. Combined with advanced functional MRI techniques such as dynamic contrast-enhanced perfusion-weighted imaging, CE-MRI also provides physiological information regarding the hemodynamics and neoangiogenic status of the CNS lesion.11

Clinically, CE-MRI is most commonly used to evaluate primary and secondary CNS tumors.3 CE-MRI of CNS tumors provides sensitive detection and an accurate description of the disease in terms of tumor grade and aggressiveness. CE-MRI is an invaluable tool for identifying critical structures for neurosurgical or radiotherapeutic intervention. In addition, it is also very useful for determining and monitoring treatment response.

Gadolinium-based MRI contrast pharmaceuticals used in clinical CE-MRI

There are various GBCAs that are either available for clinical use in humans or under development at various stages of investigation.1,6,11,17 They can be classified based on their molecular structures or physicochemical properties. For clinical applications, these GBCAs are most commonly classified based on their in vivo tissue distribution: extracellular, intracellular, tissue-specific, or blood pool/intravascular contrast agents (Table 2).1,3,6,11,17,18 There are nine GBCAs approved for intravenous administration for CE-MRI. Seven of these agents are approved for use in CE-MRI of the CNS. All of these agents are non-specific extracellular agents and lack specificity for typing cancers for the purpose of differential diagnosis.13,14

Gadopentetate dimeglumine (Gd-DTPA) was the first intravenous MRI contrast agent used clinically, and a number of similar Gd chelates have been developed in an effort to further improve clinical efficacy, patient safety, and patient tolerance.6,7 The major chemical differences among these GBCAs are the presence or absence of overall charge, ionic or nonionic, and their ligand frameworks (linear or macrocyclic) (Table 3).3,18,19

Some important properties of GBCAs are high solubility, high relaxivity, low toxicity, low osmolality, thermodynamic and kinetic stability, and number of water coordination sites.2,7,18,20,21 Chemically, hydrophilicity is important because high overall hydrophilicity is associated with very low protein binding and good biological tolerance. All GBCAs are nine-coordinate complexes in which a ligand occupies eight binding sites at the Gd3+ metal center, and the ninth coordination site is occupied by a water molecule. Kinetic stability is an important factor as related to the safety of GBCAs in causing nephrogenic systemic fibrosis (NSF).18,19,22,23 The kinetic stability is generally related to the potential dechelation reaction or transmetallation of the GBCAs that results in the release of the toxic free Gd3+ in vivo. Idee et al18 proposed three classes of GBCAs based on their experimentally determined in vitro results in the presence of Zn2+ at pH 7.4 (Table 2).19,22,23 The classes are as follows:

1. macrocyclic chelates (Gd-DOTA, Gd-HP-DO3A, and Gd-BT-DO3A) with very high kinetic stability;
2. ionic, open-chain chelates (Gd-DTPA, Gd-BOPTA) with moderate kinetic stability;
3. nonionic, open-chain chelates (Gd-DTPA-BMA and Gd-DTPA-BMEA) with poor kinetic stability.

Both renal and extrarenal toxicities have been reported following the clinical use of GBCAs in patients with underlying kidney disease.24–26 In 2007, the United States Food and Drug Administration requested that all manufacturers of GBCAs add new warnings about how exposure to GBCAs increases the risk for NSF in patients with advanced kidney disease. The stability of GBCAs appears to be an important factor in the pathogenesis of NSF.7 It is postulated that GBCAs of relatively low stability may release free Gd3+ ions that lead to the initiation of the fibrosis process. Idee et al18 suggested that high kinetic stability combined with a

high thermodynamic stability can minimize the amount of free Gd\(^{3+}\) in vivo.

### Development of gadobutrol

Based on the aforementioned physicochemical properties required for a clinically useful GBCA, Gd-BT-DO3A was developed for lower toxicity and higher dose concentration. Gd-BT-DO3A has a macrocyclic framework and is neutral.\(^{21,27}\) The BT-DO3A ligand was developed based on the belief that high overall hydrophilicity of an agent is generally associated with very low protein binding and good biological tolerance.\(^{21}\) It is a modification of the Gd-DOT A compound in which a trihydroxybutyl group is attached to the macrocyclic ligand to ensure high hydrophilicity. The ligand contains two chiral carbons at C-13 and C-14, and therefore the product is a racemic mixture of (13R,14S)- and (13S,14R)-. The Gd(III) in Gd-BT-DO3A has a coordination number of 9. Gd-BT-DO3A is a water-soluble, highly hydrophilic compound with a partition coefficient between n-butanol and buffer at pH 7.6 of \(-0.006.28\).

Gd-BT-DO3A was first synthesized by Vogler et al\(^{29}\) based on the general method for preparing the macrocyclic core using the Richman–Atkins method. Later, Platzek et al\(^{21}\) described three approaches to synthesizing the BT-DO3A ligand. One approach was preferred because it involved fewer steps and allowed scaled-up production for clinical applications. In this approach, 1-(1-[hydroxymethyl]-2,3-dihydroxypropyl)-1,4,7,10-tetraazacyclododecane tetrahydrochloride was first prepared. The compound was then reacted with chloroacetic acid at 70\(^{\circ}\)C and pH 9–10 for 18 hours. Gd-BT-DO3A was then prepared by adding Gd\(_2\)O\(_3\) to the ligand in water and stirring at 90\(^{\circ}\)C for 6 hours. Cation and anion exchange resins were then added at room temperature, and the mixture was stirred for 30 minutes. The resins were recollected by filtration, and charcoal was added to the filtrate and refluxed for 1 hour. The solution was filtered and evaporated to dryness. The residue was re-dissolved in water and ethanol, and then was refluxed for 2 hours. Gd-BT-DO3A was collected by filtration and drying under vacuum (12 hours at 60\(^{\circ}\)C). The final yield was 87%.

### In vitro and preclinical animal studies of Gd-BT-DO3A

Pintaske et al\(^{30}\) determined the in vitro relaxivity of Gd-BT-DO3A and other compounds (Gd-DTPA and Gd-BOPTA) in human plasma obtained from healthy volunteers. Measurements of Gd-BT-DO3A in concentrations of 0.01 mM up to 64 mM at 37\(^{\circ}\)C were made with 0.2-, 1.5-, and
3.0-Tesla (T) clinical scanners. The longitudinal relaxation rates ($T_1$; liter × mmol$^{-1}$ × s$^{-1}$) of Gd-BT-DOTA were 5.5 ± 0.3, 4.7 ± 0.2, and 3.6 ± 0.2, at 0.2, 1.5, and 3 T, respectively. The transverse relaxation rates ($T_2$; liter × mmol$^{-1}$ × s$^{-1}$) were 10.1 ± 0.3, 6.8 ± 0.2, and 6.3 ± 0.3, at 0.2, 1.5, and 3 T, respectively. In comparison, these values were lower for Gd-DTPA but higher for Gd-BOPTA.

Vogler et al. measured the in vivo physicochemical properties of Gd-BT-DOTA. The osmolality was found to be 0.57 osmol/kg for the 0.5 M concentration and 1.39 osmol/kg for the 1 M concentration. The distribution coefficient (butanol/water) was 0.006, and the viscosity was 1.43 cP for the 0.5 M concentration and 3.7 cP for the 1 M concentration. The $T_1$-relaxivity (liter × mmol$^{-1}$ × s$^{-1}$) in plasma was determined to be 5.6 at 0.45 T and 6.1 at 2 T. There was negligible protein binding of about 2.7% in plasma. With use of rat mast cells, the $I_{50}$ (the concentration at which histamine was released) was found to be greater than 250 mM. The $I_{50}$ value for lysozyme inhibition (the concentration at which 50% of the enzyme was inhibited) was greater than 300 mM.

Vogler et al.29 studied the long-term elimination and biodistribution of 0.25 mmol/kg Gd-BT-DOTA in rats. More than 90% of the intraperitoneally injected dose (ID) was excreted by the kidneys in 2 hours and 100% in 7 days. The total amount remaining in the body decreased from 0.71% ID on day 1 to 0.15% ID on day 7 after injection. The acute toxicity (lethal dose [LD$_{50}$]) in mice was 23 mmol/kg. In a similar study at 1.5 T MRI, the same group of investigators37 also found consistently greater tumor enhancement produced by Gd-BE-DOTA than those of Gd-DTPA and Gd-DOTA. Kramer et al.38 also found Gd-BT-DOTA (0.1 mmol/kg) produced significantly higher CNR and SNR than Gd-DOTA (0.15 mmol/kg) in a rat brain glioma model at 1.5 and 3 T MRI.

Vogler et al.29 performed Gd-BT-DOTA pharmacokinetics studies in beagle dogs. The elimination $t_1/2$ and the plasma clearance were 45 ± 3.6 minutes and 3.75 ± 0.30 mL/minute/kg, respectively. The total volume of distribution at steady state ($V_d$) was 0.23 ± 0.02 L/kg. High-performance liquid chromatography analysis of the plasma and urine samples showed that Gd-BT-DOTA was not metabolized.

Clinical studies of Gd-BT-DOTA

Staks et al.39 investigated the pharmacokinetics, dose proportionality, and tolerability of Gd-BT-DOTA in healthy volunteers. Two double-blind, randomized, placebo-controlled Phase I studies were conducted for testing a low concentration (0.5 M; doses = 0.04, 0.1, 0.2, 0.3, and 0.4 mmol/kg; $n = 55$) and a high concentration (1 M; doses = 0.3, 0.4, and 0.5 mmol/kg; $n = 36$). From the data for 24 volunteers, pharmacokinetic parameters were calculated from an open two-compartment model. The values for plasma elimination half-life ($t_{1/2p}$), $V_d$ (liter/kg), renal clearance (mL/min/kg), and 72-hour total renal excretion (Urine, 72 hours [% ID]) for a 0.1 mmol/kg dose were 1.78 ± 0.43, 0.21 ± 0.02, 1.56 ± 0.18, and 98 ± 3.33, respectively. For a 0.4 mmol/kg dose, these values were 1.33 ± 0.21, 0.15 ± 0.02, 1.45 ± 0.22, and 96.6 ± 5.61, respectively. Plasma Gd-BT-DOTA was shown to be ineffective in providing contrast enhancement for MRI imaging study. Doses of 0.1 and 0.2 mmol/kg were studied.
in 12 male healthy volunteers. It was reported that both agents achieved similarly high-quality, diagnostically valid perfusion maps.

Tombach and Heindel\(^{41}\) and Huppertz and Rohrve\(^{42}\) summarized studies for the clinical applications of 1 M Gd-BT-DO3A. In 29 Phase I to Phase III studies (2523 subjects and 2662 doses), Gd-BT-DO3A was distributed in the extracellular fluid with a plasma terminal \(t_{1}\) of 1.7–2 hours. Approximately 98% of the dose was excreted unchanged in the urine within 12 hours. The studies indicated that 1 M Gd-BT-DO3A had an excellent safety profile with doses ranging from 0.04 to 1.5 mmol/kg. Overall, 8.5% of the patients reported related and unrelated adverse events. For contrast enhancement, analysis of efficacy data showed results comparable to results of other commercially available 0.5 M Gd-chelates in studies of the CNS (677 patients) and angiography (676 patients). In a study of the pharmacokinetics of 1 M Gd-BT-DO3A in 21 patients with chronic renal failure, Tombach et al\(^{43}\) reported that the extracellular distribution of Gd-BT-DO3A remained unchanged but the mean elimination \(t_{1}\) increased compared with that of healthy volunteers. Hahn et al\(^{44}\) studied the pharmacokinetics and safety of Gd-BT-DO3A in 130 pediatric patients aged 2–17 years. The authors concluded that no adjustment for the adult dose of 0.1 mmol/kg is necessary for this age range and that Gd-BT-DO3A was safe and well tolerated in the study.

Anzalone et al\(^{45}\) and Kim et al\(^{46}\) compared 1 M Gd-BT-DO3A with 0.5 M Gd-DTPA in their clinical performance of detecting brain metastases at 1.5 T MRI. At equal Gd dosage (0.1 mmol/kg), Anzalone et al\(^{45}\) reported that Gd-BT-DO3A appeared to produce improved lesion conspicuity in ten out of the same group of 27 patients with at least one cerebral metastasis. Using double doses (0.2 mmol/kg) of both Gd-BT-DO3A and Gd-DTPA, Kim et al\(^{46}\) found Gd-BT-DO3A detected 25 additional lesions than that of Gd-DTPA (130 lesions) in the same 27 patients. The mean CNR was significantly higher \((P = 0.00011)\) with Gd-BT-DO3A \((2.17 \pm 0.19)\) than that of Gd-DTPA \((1.9 \pm 0.26)\).

In a multicenter, Phase II/III study of comparing 1 M Gd-BT-DO3A with 0.5 M Gd-HT-DO3A (0.2 mmol/kg), Katakami et al\(^{47}\) studied the efficacy and safety of two doses of Gd-BT-DO3A (0.1 and 0.2 mmol/kg) at 1.5 and 3 T MRI in 175 patients with brain metastases. The mean number of detected lesions per patient was 6.28, 6.92, and 6.87 for Gd-BT-DO3A (0.1 mmol/kg), Gd-BT-DO3A (0.2 mmol/kg), and Gd-HT-DO3A, respectively. Overall clinical performance of Gd-BT-DO3A at both 0.1 and 0.2 mmol/kg was very similar to the 0.2 mmol/kg Gd-HT-DO3A. Another multicentric randomized intraindividual crossover comparison of 1 M Gd-BT-DO3A with 0.5 M Gd-DOTA in 136 brain tumor patients at 1.0 T MRI was reported by Anzalone et al.\(^{48}\) At the dose of 0.1 mmol/kg Gd-BT-DO3A, there was a significantly higher qualitative and quantitative preference by independent blinded readers for Gd-BT-DO3A when compared to Gd-DOTA.

Voth et al\(^{52}\) reviewed and performed an integrated analysis of 34 clinical trials to assess the safety and tolerability of Gd-BT-DO3A. The review involved 4549 patients treated with gadobutrol for various clinical indications, including the CNS imaging \((n = 2292)\). These trials were prospectively planned and conducted between the years of 1993 and 2009. A majority of the patients \((n = 2434)\) received the generally recommended dose of 0.1 \((\pm 0.01)\) mmol/kg body weight. The rest of the patients received from less than 0.09 to 0.51 mmol/kg body weight. Out of the total enrolled patients, 182 (4.0%) reported one or more adverse events. Out of all patients who had CNS imaging, 106 (4.6%) also reported one or more adverse events. In comparison, 74 (4.0%) AEs were reported in 1822 patients treated with similar GBCAs (Gd-DTPA, \(n = 912\); Gd-HP-DOTA, \(n = 555\); Gd-DTPA-BMEA, \(n = 227\); Gd-DTPA-BMA, \(n = 150\)).

The most common AEs were headache, nausea, fever, and dysgeusia. Similar incidence rates were observed in pediatric patients (5.8%), patients with severe or moderate renal impairment (2.5%), patients with severe or moderate hepatic impairment (4.2%), and patients with cardiovascular disorders (2.8%). A review of post-marketing surveillance data from more than 5.7 million estimated gadobutrol administrations showed a total of 1175 (0.02%) AEs were reported. There were ten reported NSF for the entire reporting period up to February 2011. The review concluded that Gd-BT-DO3A has an excellent safety profile and a positive benefit risk profile when used in clinically indicated CE-MRI.

### A potential advantage of using gadobutrol in CE-MRI of the brain

Gd-BT-DO3A is a non-ionic, macrocyclic GBCA and was first approved in 1998 for clinical use in Switzerland. It is now approved for clinical use in 66 countries worldwide, including the EU, USA, Australia, Canada, China, South Africa, Mexico, New Zealand, Turkey, and some Eastern European and Asian countries.\(^{53}\) Gd-BT-DO3A is composed of a macrocyclic structure which has been shown to be more kinetically stable in vitro than GBCAs with linear, open-chain structures. This high stability may minimize the possibility of free toxic Gd\(^{3+}\) ions being released in vivo. Preclinical and clinical studies have shown that it has at least equivalent if
not better efficacy and safety profiles to other similar GBCAs. However, Gd-BT-D03A has a distinguishing feature that it is the only clinical agent commercially available in a formulation of 1.0 M concentration (Table 2). With this higher Gd concentration, Gd-BT-D03A at 1.0 M has the highest in vitro T1 shortening effect per unit volume compared with other GBCAs at 0.5 M. Clinically, the double concentrated Gd-BT-D03A allows for injection volume reduction without dose level changes and the compact bolus injected is better defined in vivo. This has been proven to be advantageous for some time-resolution MRI studies such as brain perfusion MRI or contrast-enhanced MRA. It is possible that even with the blood dilution and circulation, the double-concentrated agent may still localize in the CNS at a relatively higher concentration than other comparable GBCAs. As a result, Gd-BT-D03A may be able to achieve better contrast enhancement of brain lesion than other similar GBCAs at the same dose level. In light of potential NSF events associated with the use of all GBCAs, the probability of increasing their clinical efficacy without exposing the patient to a higher dose level may make this advantage more significant. Recent published multicenter clinical trials appeared to support this potential advantage of using Gd-BT-D03A for CE-MRI of the brain. However, there is insufficient evidence to suggest that the use of Gd-BT-D03A will decrease the incidence of adverse events associated with the use of GBCAs.
