Background: Cerium dioxide (CeO₂) nanoparticles have potential therapeutic applications and are widely used for industrial purposes. However, the effects of these nanoparticles on primary human cells are largely unknown. The ability of nanoparticles to exacerbate pre-existing inflammatory disorders is not well documented for engineered nanoparticles, and is certainly lacking for CeO₂ nanoparticles. We investigated the inflammation-modulating effects of CeO₂ nanoparticles at noncytotoxic concentrations in human peripheral blood monocytes.

Methods: CD14⁺ cells were isolated from peripheral blood samples of human volunteers. Cells were exposed to either 0.5 or 1 µg/mL of CeO₂ nanoparticles over a period of 24 or 48 hours with or without lipopolysaccharide (10 ng/mL) prestimulation. Modulation of the inflammatory response was studied by measuring secreted tumor necrosis factor-alpha, interleukin-1beta, macrophage chemotactic protein-1, interferon-gamma, and interferon gamma-induced protein 10.

Results: CeO₂ nanoparticle suspensions were thoroughly characterized using dynamic light scattering analysis (194 nm hydrodynamic diameter), zeta potential analysis (−14 mV), and transmission electron microscopy (irregular-shaped particles). Transmission electron microscopy of CD14⁺ cells exposed to CeO₂ nanoparticles revealed that these nanoparticles were efficiently internalized by monocytes and were found either in vesicles or free in the cytoplasm. However, no significant differences in secreted cytokine profiles were observed between CeO₂ nanoparticle-treated cells and control cells at noncytotoxic doses. No significant effects of CeO₂ nanoparticle exposure subsequent to lipopolysaccharide priming was observed on cytokine secretion. Moreover, no significant difference in lipopolysaccharide-induced cytokine production was observed after exposure to CeO₂ nanoparticles followed by lipopolysaccharide exposure.

Conclusion: CeO₂ nanoparticles at noncytotoxic concentrations neither modulate pre-existing inflammation nor prime for subsequent exposure to lipopolysaccharides in human monocytes from healthy subjects.

Keywords: cerium dioxide, nanoparticle, nanomedicine, inflammation, human monocyte, lipopolysaccharides

Introduction
Nanomedicine is expected to benefit from cerium dioxide (CeO₂) nanoparticle use in antioxidant therapy,¹ neuroprotection,² radioprotection,³ and ocular protection.⁴ Apart from these nanomedicinal uses, various industrial applications of CeO₂ nanoparticles include catalysis,⁵ ultraviolet absorbance,⁶,⁷ oxygen sensing,⁸ solar and fuel cells,⁹ and polishing (for glasses, lenses, television tubes, fuel cells, and precision optics).¹⁰ Moreover, CeO₂ nanoparticles have significant environmental health significance due to their widespread use as a diesel fuel additive. Indeed, it has been documented that addition of CeO₂ to diesel decreases fuel consumption by 5%–8% and...
emission of combustion-derived nanoparticles and unburned hydrocarbons by up to 15%.11,12 However, the accompanying release of CeO$_2$ nanoparticles into the environment could exert unexpected health effects.13 For this reason, the Organization for Economic Cooperation and Development has included CeO$_2$ nanoparticles in the priority list of nanomaterials requiring urgent evaluation.14

Most human diseases are associated with local or systemic inflammatory responses. Moreover, exposure to environmental proinflammatory agents is ubiquitous; for example, we are all exposed to bacterial lipopolysaccharides, either through ingestion (contaminated food or water) or inhalation (house dust, particulate matter, diesel exhaust particles). Furthermore, many epidemiological and experimental studies have shown that individuals with pre-existing inflammatory conditions are more prone to the adverse effects of environmental injury.15–17 Indeed, aggravation of pre-existing inflammation has been documented after exposure to particulate air pollution and various types of nanoparticles.18–21

This study was designed to investigate the inflammation-modulating effects of CeO$_2$ nanoparticles in human peripheral blood monocytes at noncytotoxic exposure concentrations. The proposed uses of CeO$_2$ nanoparticles in nanomedicine make peripheral blood monocytes important target cells at the portal of entry of nanoparticles into the human body. These cells are an essential link between the adaptive and innate immune responses because they develop into various forms of antigen-presenting cells (macrophages, dendritic cells). We show here that noncytotoxic exposures to CeO$_2$ nanoparticles do not prime or aggravate pre-existing lipopolysaccharide-induced inflammation.

**Materials and methods**

**Study subjects and isolation of cells**

This study was approved by the National Institute of Environmental Health Sciences institutional review board. Adult human volunteers without any history of a chronic medical condition (hepatitis B, hepatitis C, or human immunodeficiency virus) and currently not taking any type of medication were recruited to the National Institute of Environmental Health Sciences Clinical Research Unit. The demographics of the study population are shown in Table 1. Recruited volunteers underwent phlebotomy, and up to 300 mL of whole blood were withdrawn from an antecubital vein into citrated tubes. Mononuclear fraction was isolated using gradient centrifugation, and CD14$^+$ cells were purified using magnetic beads according to the manufacturer’s recommendations (Miltenyi Biotec, Boston, MA). By this method, 95%–99% viable pure human monocytes were obtained, confirmed by flow cytometry and cytopsin preparations.

**Cells and culture conditions**

After isolation, the cells were seeded in 24-well cell culture plates (400,000 cells per well) in x-vivo™ cell culture medium (Lonza, Walkersville, MD) supplemented with 1% human serum and antibiotics (1% solution of penicillin 100 µg/mL and streptomycin 100 µg/mL; Invitrogen Carlsbad, CA) and incubated at 37°C, 5% CO$_2$, and 95% relative humidity for 2 hours (to allow sufficient time for attachment of cells). After cell attachment, the cell culture medium was aspirated and the cells were washed thoroughly with fresh medium to remove unattached cells. The cells were then incubated in fresh prewarmed medium containing the desired doses of nanoparticles or lipopolysaccharides for the different time intervals (24 or 48 hours).

**Nanoparticles**

CeO$_2$ nanoparticles were obtained from Meliorum Technologies (Rochester, NY) and characterized in the Center for Environmental Implications of Nanotechnology, University of California. Studied characteristics included shape/diameter (transmission electron microscopy), crystal structure (X-ray diffraction analysis), surface area (Brunauer–Emmitt–Teller method), suspension behavior, hydrodynamic diameter, and size distribution (dynamic light scattering), zeta potential (ZetaSizer Nano; Malvern Instruments, Westborough, MA), purity (thermogravimetric analysis), and bacterial endotoxins (limulus amebocyte lysate assay). Dynamic light scattering analysis of the CeO$_2$ nanoparticle suspensions (at 1 µg/mL) in cell culture medium was done to determine the size distribution. A nanoparticle stock solution (1 mg/mL) was prepared in water and stored at 4°C in a refrigerator. All exposure suspensions were freshly prepared from this stock solution after sonication at three pulses of 20 seconds at 235 W with a 5-second pause using a Mesonix S 4000 cup horn sonicator (Qsonica LLC, Newtown, CT). After sonication, the particles were suspended in cell culture medium and used to expose cells within 5 minutes after vortexing.

These are the best known commercially available CeO$_2$ nanoparticles which have been widely explored in various

fields (toxicology, biology, nanotechnology) and have an excellent publication record. From an environmental perspective, study of these particles is very valid because the particles and their aggregates lie within the range of respirable particles (less than 3 μm) which can deposit in the alveolar regions of the lungs.

**Experimental design**

A low effective dose of lipopolysaccharides (Escherichia coli O111:B4, 10 ng/mL) was used to induce an inflammatory response in the cells. The total duration of the experiments was fixed to either 24 or 48 hours and the ability of the nanoparticles to modulate pre-existing inflammation or to prime for subsequent inflammation was assessed. A graphical description of the protocols is given in Figure 1. To assess the ability of the nanoparticles to modulate pre-existing inflammation, the cells were incubated with lipopolysaccharides for 16 hours and then exposed to CeO2 nanoparticles for 8 hours (24-hour protocol) or 32 hours (48-hour protocol). On the other hand, to assess the ability of the nanoparticles to prime for subsequent exposure to inflammatory agents, the cells were exposed to CeO2 nanoparticles for 16 hours and then exposed to lipopolysaccharides for 8 hours or 32 hours (for the 24-hour and 48-hour protocols, respectively).

**Transmission electron microscopy for nanoparticle-cell interaction**

Cells were grown in two-chamber cell culture slides and treated with 0.5 or 1 μg/mL CeO2 nanoparticles for 24 hours. The cells were fixed in 3% glutaraldehyde and processed for transmission electron microscopic analysis. Thin sections (60–90 nm) were cut and placed on Formvar copper grids then stained with uranyl acetate and lead citrate. After staining, sections were examined on a FEI Tecnai 110 kV microscope at 80 kV and digital photomicrographs were taken.

**Toxicity analysis**

A propidium iodide incorporation assay was performed to evaluate membrane integrity and cytotoxicity. Briefly, cells were trypsinized after 24-hour or 48-hour exposures using trypsin-EDTA. The action of trypsin was inhibited using 10% fetal bovine serum, and the cells were centrifuged at 960 rpm for 6 minutes. Cells were resuspended in 500 μL of warm cell culture medium containing 2.5 μg/mL of propidium iodide. Analysis was performed on a FACSArray II (BD Biosciences, Franklin Lakes, NJ) instrument at 488 nm excitation and 610 nm emission wavelengths. After elimination of cellular debris, at least 10,000 cells were analyzed to determine the percentage of propidium iodide-positive cells.

**Measurement of cytokines**

At the end of the desired incubation time, the supernatants were recovered, centrifuged at 10,000 g for 15 minutes at 4°C, and stored at −80°C till further analysis. The concentration of tumor necrosis factor alpha (TNF-α) was evaluated using a commercially available human enzyme-linked immunosorbent assay kit (R&D Systems, Minneapolis, MN) according to the manufacturer’s recommendations. The concentrations of interleukin-1β (IL-1β), macrophage chemotactic protein-1, IP-10, and interferon-gamma (INF-γ) were determined using the BD Bioplex assay system (BD Biosciences).

**Statistical analysis**

Data are presented as the mean ± standard error of the mean and were analyzed by analysis of variance, followed by Tukey’s test using GraphPad (GraphPad Prism 4.01, GraphPad Software Inc, San Diego, CA). A level of P < 0.05 (two-tailed) was considered to be statistically significant.

**Results**

**Nanoparticle characteristics**

The nanoparticle characteristics are presented in Table 2 and Figure 2. Transmission electron microscopic analysis revealed that the CeO2 nanoparticles were irregular in shape and tended to aggregate (Figure 2A). The X-ray diffraction analysis pattern is shown in Figure 2B, demonstrating that the particles are highly crystalline and all peaks could be indexed to cubic fluorite CeO2. Dynamic light scattering analysis revealed that the CeO2 nanoparticles (1 μg/mL)
suspended as a single (96 nm size) population in x-vivo cell culture media supplemented with 1% heat inactivated human serum. Further, these particles had $-13$ mV zeta potentials in the same suspension.

**CeO$_2$ nanoparticles are internalized by human monocytes**

Transmission electron microscopic analysis of nanoparticle-cell interactions indicated that the CeO$_2$ nanoparticles were taken up by human monocytes either in vesicles/phagosomes (mixed with the other debris) or were free in the cytoplasm (Figure 3).

**CeO$_2$ nanoparticles induce cytotoxicity**

The cytotoxic potential of CeO$_2$ nanoparticles was tested using propidium iodide staining (Figure 4). Figure 4A shows the cytotoxic response after exposure to different doses of CeO$_2$ nanoparticles. We demonstrated that CeO$_2$ nanoparticles induce a cytotoxic response at doses $>1$ µg/mL (Figure 4A). We therefore decided to use only the lower doses ($\leq1$ µg/mL) for our inflammatory response experiments. We confirmed that addition of 10 ng/mL lipopolysaccharides to these doses of CeO$_2$ did not alter cytotoxicity (Figure 4B).

**CeO$_2$ nanoparticles do not modulate inflammatory response to lipopolysaccharides**

The ability of CeO$_2$ nanoparticles to modulate or prime the inflammatory response to lipopolysaccharides was assessed using the protocol described in Figure 1. As presented in Figure 5, we did not find any significant difference in the production of TNF-$\alpha$, a proinflammatory cytokine, after CeO$_2$ nanoparticle exposure. A similar pattern was observed for IL-1$\beta$ production (Figure 6). IFN-$\gamma$ and IP-10 also showed a similar trend, and the results are presented in Table 3. Macrophage chemotactic protein-1 production was increased by lipopolysaccharide exposure only at 24 hours and this increase was no longer detected at 48 hours.

**Discussion**

Nanotechnology has shown promising potential to improve the quality of everyday life and has led to the production of a variety of novel materials for industrial, consumer product, and medicinal applications. However, there is a lack of adequate data about the effects of these nanomaterials on human health and the environment. In particular, the effects of these novel materials on susceptible populations (with pre-existing health issues) are rarely addressed. Evaluation of such effects becomes even more pertinent when considering the proposed use of nanomaterials in the medical sector. This experimentation aimed at: elucidating the inflammatory potential of CeO$_2$ nanoparticles; evaluating the possibility of aggravation of a pre-existing inflammatory response after exposure to CeO$_2$ nanoparticles; and exploration of the ability of CeO$_2$ nanoparticles to prime for subsequent exposure to an inflammatory agent. Our results indicate that CeO$_2$ nanoparticles do not significantly change the lipopolysaccharide-induced inflammatory responses of peripheral blood monocytes at noncytotoxic doses. Moreover, CeO$_2$ nanoparticles did not prime human monocytes for subsequent exposure to lipopolysaccharides.

Controversy exists in the published literature about the inflammatory effects of CeO$_2$ nanoparticles. Hirst et al reported anti-inflammatory effects by demonstrating reduction of inducible nitric oxide expression in J774A.1 macrophages$^{22}$ and Niu et al reported suppression of inflammatory mediators (macrophage chemotactic protein-1, IL-6, and TNF-$\alpha$) production by CeO$_2$ nanoparticles in a murine cardiomyopathy model. Furthermore, CeO$_2$ nanoparticles have been reported to reduce oxidative signaling and cell death induced by cigarette smoke, diesel exhaust, and hydrogen peroxide.$^{24-26}$ In contrast, other in vitro and in vivo experiments suggest that CeO$_2$ nanoparticles produce inflammation, reactive oxygen species, lipid peroxidation, liver and lung damage, acute and chronic fibrotic effects, and altered macrophage phenotypes.$^{27-31}$ Variation in target species/cell type, experimental design (exposure concentration and duration) and nanoparticle characteristics (shape, size, purity,

agglomeration, and surface modifications) could be possible reasons for these differences and make cross-study comparisons difficult. Further, CeO$_2$ nanoparticles can be prepared by different methods that lead to differences in relative proportions of Ce$^{3+}$/Ce$^{4+}$ ions (one of the reasons proposed for CeO$_2$ nanoparticle-induced reactive oxygen species scavenging).$^{32}$ Nevertheless, we did not observe any significant differences in cytokine release of human immune cells after exposure to noncytotoxic doses of CeO$_2$ nanoparticles.

The present study is unique in the sense that it addresses the question of pre-existing inflammatory conditions in human cells which are likely to exist in the event of therapeutic application of CeO$_2$ nanoparticles. Indeed, it has already been suggested that during the development of therapeutic nanomaterials, their biocompatibility should also be evaluated in the presence of other agonists such as lipopolysaccharides.$^{33}$ Moreover, studies in mice and in cell lines may not accurately predict nanoparticle-elicited responses in primary human cells. Lastly, CeO$_2$ nanoparticle-induced protective effects have been reported in oxidative stress-dependent processes, but no attempt has been made to explore the possibility of similar effects on oxidative stress-independent mechanisms (such as lipopolysaccharide-induced inflammatory responses). Our study addresses these gaps in our knowledge. Our data suggest that pre-existing inflammation does not seem to alter the response to CeO$_2$ nanoparticles significantly. On the other hand, we did not find any beneficial effect of CeO$_2$ nanoparticles on lipopolysaccharide-induced cytokine release, suggesting that the previously reported antioxidant effects of CeO$_2$ nanoparticles in macrophages may be limited in their scope of action, and do not extend to a general downregulation of the inflammatory response.

We did find CeO$_2$ nanoparticle internalization by human monocytes, either in the form of vesicles or free in cytoplasm.
These results are in agreement with previous studies reporting endocytosis of CeO$_2$ nanoparticles into cells. These results indicate that CeO$_2$ nanoparticles have good biocompatibility at the tested concentrations and their presence inside the cells did not influence the production of the cytokines studied.

We and others have previously shown that nanoparticles can adsorb cytokines and other biologically significant proteins (for example, enzymes) onto their surfaces and thus may interfere with accurate assessment of their inflammatory potential. We checked the possibility of TNF-α binding by incubating the nanoparticles with a known concentration of TNF-α for 24 or 48 hours and reanalyzing the concentrations of cytokines by enzyme-linked immunosorbent assay. We did not find any difference between untreated and nanoparticle-treated samples, indicating that CeO$_2$ nanoparticles did not adsorb cytokines.

Our study does have certain limitations. These include use of lipopolysaccharide priming (which can skew the inflammatory responses towards Th1) and use of Th1 cytokines only to assess inflammation. However, this does not limit the scope of our study because lipopolysaccharide exposure is well described and one of the best environmentally

relevant models available in which to conduct inflammation modulation studies. More in vivo studies are in progress to study Th1/Th2 polarization of responses and to elaborate the possibilities of modulation of allergic lung inflammation after exposure to CeO₂ nanoparticles.

**Conclusion**

Overall, our results suggest that, under noncytotoxic exposure conditions, CeO₂ nanoparticles neither modulate nor prime for a lipopolysaccharide-induced inflammatory response in human peripheral blood monocytes. Our results emphasize the need to evaluate the effects of nanomaterials in the presence of agonists (such as lipopolysaccharides) which are expected to occur in real-life conditions. In the future, further studies on primary human cells focusing on susceptible populations (with pre-existing diseases) are warranted for identification of the realistic hazards of nanomaterials.
