Abstract: Osteoarthritis (OA) is a physically and emotionally debilitating disease that predominantly affects the aging adult population. Current pharmacologic treatment options primarily consist of nonsteroidal anti-inflammatory drugs and/or acetaminophen, but associated side effects, analgesic limitations, especially in the elderly, and the need for around-the-clock analgesia have led physicians to search for alternative analgesics. Opioids have shown effectiveness at mitigating both chronic cancer and noncancer pain, and their ability to be placed into controlled release (CR) formulations suggests that they may prove efficacious for OA patients. One formulation, oxycodone CR, has shown effectiveness in cancer pain patients and in some trials of noncancer low back pain. In this review, the objective was to synthesize the reported findings by researchers in this field and present an up-to-date look at the efficacy, safety, and tolerability of oxycodone CR in OA patients. Public literature databases were searched using specific keywords (eg, oxycodone CR) for studies assessing the efficacy and safety profile of oxycodone CR and its use in patients with OA. A total of eleven articles that matched the criteria were identified, which included three placebo-controlled trials, six comparative trials, one pharmacokinetic study in the elderly, and one long-term safety trial. Analysis of the studies revealed that oxycodone CR is reasonably efficacious, safe, and tolerable when used to manage moderate to severe chronic OA pain, with similar side effects to that of other opioids.

Keywords: oxycodone, extended release, controlled release, opioid, osteoarthritis

Introduction

Osteoarthritis is a common joint disorder among the older adult population. One in four adults over the age of 65 worldwide are affected by this disease, and the prevalence has been reported to be 27.2%, 13.8%, and 27.0% in hands, knees, and hips, respectively. It is a disease that ultimately leads to destruction of the cartilage and the bone in the joints, and can be a result of a number of factors besides age including genetics, gender, race, weight, and diet. Severe chronic pain is known to be associated with the disease and contributes substantially to a patient's disability, in addition to having a negative impact on motor function, sleep, mood, and overall quality of life. Thus, a major goal of therapy has been for the control of pain.

Osteoarthritis is comprised of a complex collection of pathophysiological processes that both individually and in combination give rise to a multifaceted variety of pain types. It includes damage and degradation of several joint structures and tissue types, such as cartilage (reduced proteoglycan content), smooth muscle, and bone. In addition, new bone outgrowths at the margins of the injury further irritate the surrounding areas (eg, a joint capsule) and recruit a cascade of more inflammatory responses. The multifactorial
combination of mechanical and biochemical insults together with inflammation lead to a pain of multifaceted etiology and type. Treatment of such a complex pain is unlikely to be successful using an analgesic regimen that relies only on one analgesic class approach. Thus, opioids, both from a mechanistic and efficacy point of view, with adequate precautions are a rational pharmacologic option for the appropriate patient and situation.

Current treatment options for reducing pain combine pharmacologic and nonpharmacologic approaches. Nonpharmacologic approaches may consist of physical and occupational therapy in addition to increasing patient awareness and education. Pharmacologic approaches usually consist of analgesic therapy. Initial analgesic therapy may consist of acetaminophen, salicylates, nonsteroidal anti-inflammatory drugs, or weak opioids (e.g., propoxyphene) and mixed-acting analgesics (e.g., tramadol). Use of these analgesics, especially acetaminophen and nonsteroidal anti-inflammatory drugs, have limitations and have been shown to be mildly effective to noneffective in some studies. Some of these limitations include an analgesic ceiling effect and any increase of dosage can lead to a number of side effects including hepatotoxicity, renal toxicity, cardiovascular effects, and gastrointestinal effects.

Such limitations have led some physicians to examine alternative analgesics for osteoarthritis. Opioids have demonstrated their effectiveness in mitigating pain related to both chronic cancer and noncancer pain and thus have recently been viewed as a viable alternative. Several reviews summarize the appropriateness, efficacy, and safety of opioid use for treatment of the pain associated with osteoarthritis. For example, McHughes and Lipman discuss opioids as an option for OA pain when other interventions are insufficient and Howes et al included a Cochrane systematic review of studies that involved trials in which patients received placebo or oral codeine, morphine, oxycodone, or oxymorphone. Both reviews concluded that the evidence from such trials supports the use of opioids as part of a comprehensive approach to the management of osteoarthritis pain.

Immediate release forms of various opioids have demonstrated efficacy and safety for use for some chronic pain conditions; however, it has been recommended that for chronic continuous pain, opioids should be administered around-the-clock in order to provide consistent pain relief. This can pose a challenge for the use of immediate release formulations as this requires a patient to frequently administer their medication in order to prevent any breaks in pain relief. To circumvent this problem and other problems associated with immediate release formulations, extended release (ER)/controlled release (CR) formulations of some opioids have been marketed. Advantages of ER opioids may include:

- Provides sustained analgesia for 12–24 hours, thus no gaps in pain relief;
- Provides consistent plasma concentrations;
- Eliminates need to wait for pain to return before taking next dose;
- May help with better nighttime pain control;
- May help increase compliance;
- Less “clock-watching”

Several oral analgesics are available in ER formulations and these include oxymorphone ER, oxycodone CR, morphine ER, tramadol ER, fentanyl transdermal, and buprenorphine transdermal. Oxycodone CR is a twice-daily (every 12 hours) formulation that has been reported to be effective in the management of cancer pain and chronic noncancer pain. Its use in osteoarthritis has been tested in both placebo-controlled and comparative studies, and a summary and evaluation of those studies is the focus of this review.

Because the management of pain for patients who have moderate to severe chronic pain related to osteoarthritis requires around-the-clock analgesia, it is reasonable to postulate that ER or CR formulations might provide patients with not only a simpler dosing schedule, but also a more consistent and enduring relief from pain. It was the objective of this review to evaluate this for an opioid that had sufficient available literature. Oxycodone CR formulation provided such an opportunity.

Methods

Literature search strategy

The strategy for the identification of studies included the electronic searching of the PubMed/MEDLINE database, EMBASE, and The Cochrane Library from database inception to December 2011. Search terms that were used included: “osteoarthritis,” “oxycodone,” “CR” [controlled release], “ER” [extended release]. Terms were selected based on the main terms in the title of the review. Terms were not used individually, but in combination in order to achieve a highly condensed and focused result list. Combinations included: “osteoarthritis AND oxycodone,” “osteoarthritis AND oxycodone AND CR,” “oxycodone AND ER,” “oxycodone AND CR,” “oxycodone AND ER.”

Selection criteria

The identified citations were then further limited to any clinical study or review article describing the safety, efficacy,
and/or tolerability of oxycodone CR for osteoarthritis. Studies that analyzed other chronic pain conditions in conjunction with osteoarthritis were also included. Studies exclusively describing only immediate release forms of oxycodone were not included. The initial literature search was performed by author RT and all articles were analyzed by all of the authors. To identify potential articles missed by the electronic search, the bibliographies of the electronically identified articles were analyzed and any appropriate article based on the title and abstract were retrieved.

Assessment of methodological quality
The quality of the articles extracted was not assessed. The goal was to present published studies regardless of the design type and quality. The intention was to present to the reader all research conducted on the current topic.

Data extraction and analysis
Data extracted from the studies included pain intensities, quality of life assessments, and adverse events (AEs). No formal statistical or meta-analysis was conducted on the studies and this task was beyond the scope of this review.

Results

Literature search
In the literature search, a total of eleven articles were identified that reviewed the safety, efficacy, and/or tolerability of oxycodone CR and its use in patients with osteoarthritis. All eleven studies were reviewed and included in this review. The studies included three placebo-controlled trials, six comparative trials, one pharmacokinetic study in the elderly, and one long-term safety trial. The comparative studies looked at oxycodone versus either oxymorphone, hydromorphone, or tapentadol.

Placebo-controlled trials of CR formulation of oxycodone
Pain intensity
In a trial of 167 patients with moderate to severe chronic osteoarthritis pain, oxycodone CR formulation was compared to placebo for up to 30 days. After a titration period using immediate release oxycodone, patients’ pain intensity decreased from 2.44 to 1.48 (P = 0.0001) on a four-point scale and was significantly superior to the placebo (P ≤ 0.05). In another trial of 133 patients using oxycodone CR (OxyContin®), daily mean pain intensity was significantly (P < 0.05) reduced at week one and week two assessment with 20 mg every 12 hours taken every day when compared to placebo. There was no difference in pain intensity throughout the day and evening, indicating a stable, continuous relief from pain. In addition, a 20% reduction in pain was achieved within 1 day of taking 20 mg every 12 hours and 2 days of taking 10 mg every 12 hours. When the trial was extended up to 72 weeks, pain intensity remained below a moderate level (less than two on a four-point scale) throughout the study. In another study conducted by Markenson et al using oxycodone CR (OxyContin) average pain intensity as measured by a ten-point Brief Pain Inventory scale was significantly reduced in the oxycodone group versus placebo (5.1 versus 6.0; P = 0.022) at visit two and (4.9 versus 6.0; P = 0.024) at 90 days, with approximately 38% of the patients achieving a 30% reduction in pain at the end of 90 days. Other Brief Pain Inventory assessments for pain including pain “right now,” “worst pain,” “least pain,” and “pain relief” were all improved from baseline values and were significantly superior to placebo. In addition, Western Ontario and McMaster University Osteoarthritis Index scores at 30 and 60 days of treatment were significantly reduced for pain (~13.0 and ~17.8 versus ~4.1 and ~2.4), stiffness (~15.8 and ~21.7 versus 0.3 and 0.1), and physical function (~12.4 and ~17.1 versus ~3.2 and ~3.8) in patients taking oxycodone CR versus placebo, respectively. Overall, pain intensity was significantly reduced in the oxycodone CR group versus placebo in all three trials indicating oxycodone CR’s effectiveness in mitigating pain in osteoarthritis.

Quality of life assessments
In a study by Caldwell et al, sleep quality was compared in patients receiving oxycodone CR versus placebo. Sleep scores improved from 2.58 to 3.57 on a five-point scale (P = 0.0001) and was significantly superior to placebo (P ≤ 0.05). In a trial of 133 patients, use of 20 mg every 12 hours oxycodone CR for up to 2 weeks significantly improved a patient’s mood, sleep, and enjoyment of life, in addition to improving the patients’ walking ability, general activity, normal work, and their relations with others. Daily activities were able to be performed with minimal to no difficulty and the patients’ performance were not impaired due to oxycodone CR. When the trial was extended up to 72 weeks, daily activities were unaffected to moderately affected by pain and their sleep was considered “fair to good,” with the number of awakenings reduced by approximately 50% after 6 months (1.7 versus 0.7). In addition, the patients’ performance on daily activities did not decline with chronic use of oxycodone CR. In the study conducted by Markenson et al, oxycodone CR significantly reduced interference...
caused by pain with various daily activities including general 
activity, mood, normal work, sleep, walking ability, and 
enjoyment of life.41 The group also assessed pain during a 
patient’s primary activity by using the Patient Generated 
Index, which is a tool to assess a patient’s satisfaction with 
activities selected by the patient as important to improve. 
The scores were significantly higher for patients on oxyc-
ocode CR versus placebo at days 30 and 45 ($P = 0.027$
and $P = 0.007$, respectively) indicating an improvement in 
the patients’ activities. Overall, patients were satisfied with 
oxycodone CR.41 Overall, patients receiving oxycodone CR 
experienced a significant improvement in various quality of 
life parameters including mood, sleep, enjoyment of life, 
and physical activity.

**AEs**

AEs associated with oxycodone CR in Caldwell et al’s 
study were those generally seen with opioids. In addition, 
the effects of nausea and dry mouth were of lower incidence 
when compared to patients on immediate release oxycodone.41 
In a trial of 133 patients, 87 (65.4%) of 133 patients reported 
at least one treatment-emergent AE during the study; the most 
common were known opioid-related side effects. A total of 
70 patients (52.6%) discontinued study participation prema-
turely, 39 because of ineffective treatment (significantly more 
in the placebo group, $P < 0.001$ for 20 mg every 12 hours) 
and 28 because of AEs (predominantly nausea, vomiting, 
and somnolence in active groups). In the long-term exten-
sion, more than 10% of the population experienced AEs that 
were related to opioids (constipation, somnolence, nausea, 
pruritus, nervousness, headache, and insomnia, with five 
patients experiencing probable drug-related serious AEs 
that resulted in hospitalization.42 In the study conducted by 
Markenson et al, AEs experienced were those typical of an 
oral opioid analgesic with a total of 28 (55%) patients in the 
placebo group and 52 (93%) of patients in the oxycodone CR 
group reporting AEs. Three serious AEs were experienced in 
the oxycodone group with 36% of the patients discontinued 
due to AEs.43 Overall, AEs experienced by patients in the 
placebo-controlled trials resembled that of other opioids, 
which included nausea, vomiting, somnolence, dry mouth, 
and constipation.

Recently a group led by Saari et al examined the age 
effects on the pharmacokinetics of oxycodone.44 The elimi-
nation half-life of intravenous oxycodone showed an age-
dependent increase from 3.8 hours to 4.6 hours in patients 
between the age of 25 years and 85 years, respectively, and 
simulations of repetitive bolus dosing showed a 20% increase 
in oxycodone concentration in the elderly. The review did 
not include a measure of AEs, so the clinical implications of 
the pharmacokinetic changes are not known, but the study 
authors suggested that dosing should be reduced and carefully 
titrated in the elderly in order to avoid excess accumulation 
of oxycodone and potentially hazardous side effects.

**Comparative trials**

**Oxymorphone ER versus oxycodone CR**

In a trial of 491 patients, two doses of oxymorphone ER were 
compared to oxycodone CR and placebo for up to 4 weeks.45 
Mean pain intensity at study visits from baseline to 3 weeks 
significantly decreased in the oxymorphone groups (20 mg 
every 12 hours or 40 mg every 12 hours) while the oxycodone 
CR (20 mg every 12 hours) trended toward significance. 
A similar assessment was made when patient diaries were 
analyzed for pain. Changes in Western Ontario and McMaster 
University Osteoarthritis Index scores for pain, stiffness, 
and physical function were statistically improved from 
baseline to week four in the oxymorphone ER groups, but 
were not for the oxycodone CR group. A total of 110 (91%) 
in the oxymorphone ER 40 mg group, 113 (95%) in the 
oxymorphone ER 20 mg group, 110 (88%) in the oxycodone 
CR 20 mg group, and 71 (57%) in the placebo group 
experienced AEs that were considered mild to moderate 
and were those typically observed with opioid treatment. 
There was a clinically meaningful greater incidence of 
nausea (60%–61% versus 43%), vomiting (23%–34% 
versus 10%), and pruritus (19%–25% versus 8%), and a 
clinically meaningful lower incidence of headache (6%–11% 
versus 18%) in the groups taking oxymorphone ER compared 
with the group taking oxycodone CR. Overall, oxymorphone 
ER proved to be superior compared to oxycodone CR in 
regard to pain intensity reduction and the occurrence of 
side effects.

**Hydromorphone ER versus oxycodone CR**

Hale et al analyzed the safety and efficacy of once-a-day 
ydromorphone ER (N = 71) to oxycodone CR (OxyContin) 
(N = 67) for up to 6 weeks for patients with moderate to 
severe osteoarthritic pain.46 Mean change in pain intensity 
on a four-point scale from baseline to end point was similar 
between hydromorphone and oxycodone ($−0.6$ versus $−0.4$,
95% confidence interval $−0.53$ to $∞$). In addition, patient 
global evaluations and their rating on overall effectiveness 
of treatment were similar. Treatment-emergent AEs occurred 
in 78.9% (56/71) of patients in the hydromorphone group.
and 79.1% (53/67) of patients in the oxycodone CR group with similar rates of discontinuation in both groups. Other studies have also shown improvement in different sleep outcomes and on the Western Ontario and McMaster University Osteoarthritis Index scale for pain, stiffness, and physical function for both hydromorphone and oxycodone CR. Overall, both hydromorphone ER and oxycodone CR are adequate for providing pain relief and have a similar risk/benefit ratio.

**Tapentadol ER versus oxycodone CR**

In a study by Afilalo et al, safety and efficacy of ER tapentadol was compared to placebo and oxycodone CR (OxyContin) for up to 12 weeks in 1023 patients. Patients were titrated for 3 weeks and then maintained for up to 12 weeks. Tapentadol ER significantly reduced average pain intensity from baseline to week twelve, whereas oxycodone CR did not. Both drugs, however, significantly reduced pain intensity through the 12-week maintenance period. A greater number of patients achieved >50% improvement in pain intensity in the tapentadol ER group (32.0% [110/344]) than in the oxycodone CR group (17.3% [59/342]; P = 0.023 versus placebo). Patients in the tapentadol ER and oxycodone CR groups, respectively, experienced at least one treatment-emergent AE (75.9% [261/344] versus 87.4% [299/342]). Incidences of constipation, nausea, vomiting, pruritus, and somnolence were significantly lower in the tapentadol group versus oxycodone.

In another study, the long-term safety and efficacy of oxycodone CR was compared to an ER formulation of tapentadol in patients with chronic pain associated with osteoarthritis of the hip and knee. A total of 894 patients received tapentadol and 223 patients received oxycodone CR for up to 1 year. Overall, 85.7% (766/824) of patients in the tapentadol ER group and 90.6% (202/223) of patients in the oxycodone CR group experienced at least one treatment-emergent AE (75.9% [261/344] versus 87.4% [299/342]). Incidences of constipation, nausea, vomiting, pruritus, and somnolence were significantly lower in the tapentadol group versus oxycodone.

The authors concluded that oxycodone ER is safe, well tolerated, and a viable option for treating chronic pain related to osteoarthritis and low back pain. Throughout a 12-month period, 823 patients received one or more doses of oxycodone ER. One or more AEs were experienced by 678 patients (82%), with the most common side effects related to opioids (constipation, nausea, and somnolence), 173 patients (21%) discontinued treatment, 133 patients (16%) decreased drug dose, and 80 patients (10%) interrupted taking the study drug because of AEs. A total of 55 patients experienced a serious AE, with five being considered related to the study drug. Mean pain intensity scores decreased significantly from baseline (6.4 to 4.5; P < 0.001). At month twelve, quality of analgesia and global assessment of study drugs were rated positively (good, very good, or excellent) by 64% and 61% of patients, respectively. The authors concluded that oxycodone ER is safe, well tolerated, and a viable option for treating chronic pain related to osteoarthritis and low back pain.

**Discussion**

The American College of Rheumatology guidelines for the treatment of osteoarthritis recommend a variety of nonpharmacologic interventions as the cornerstone of therapy. Pain management is most effective when combined with nonpharmacologic strategies. Patients with severe pain who do not respond to, or cannot tolerate, other analgesics may be considered for more potent opioid therapy. Chronic opioid therapy may be effective therapy for carefully selected and monitored patients with chronic noncancer pain.

Caring for patients struggling with moderate to severe chronic osteoarthritis pain requires the clinician to carefully weigh the benefits and disadvantages of long-term opioid therapy and to select the appropriate opioid product. Pharmacokinetic conclusions that intravenous oxycodone CR has a significantly longer half-life in older versus younger patients (3.8 hours in 25 year olds and 4.6 hours in 85 year olds) is not surprising but concerning, although one cannot draw conclusions about the use of oral oxycodone from this study. Age-dependent pharmacokinetic differences have been observed and mean that oxycodone, and indeed other opioids, must be used prudently and under close clinical supervision in the elderly, that is, the population most likely to suffer from osteoarthritis pain. Oxycodone CR clearly offered significant pain relief when compared to placebo, but that relief was associated with the typical side effects of opioid agents: constipation, somnolence, pruritus, nausea, nervousness, headache, and insomnia. Such side effects can often be successfully managed, but it is important to recognize that in these studies, some patients experienced possibly drug-related serious AEs.

Several of these studies showed durable analgesia with oxycodone CR and patients reported being satisfied with the treatment, which reportedly did not adversely impact their ability to carry out the activities of everyday living. Quality of life improvements along with better sleep and mood were reported with oxycodone CR. These are important findings, in that patients with moderate to severe osteoarthritis pain require long-term, even lifelong, pain management.

When oxycodone CR was compared to specific other analgesics (oxycodone ER, oxymorphone, hydromorphone, and tapentadol), oxycodone CR was not found to be significantly safer or more effective. Oxymorphone offered greater pain relief; tapentadol patients had fewer side effects. However, the current review mixed studies with different objectives and designs. It is reasonable to conclude that oxycodone CR offered similar, but not superior, safety and efficacy compared to the aforementioned agents.

The literature reviewed supports the fact that oxycodone CR is safe and effective and significantly reduces moderate to severe chronic pain in osteoarthritis patients with the expected side effects associated with other opioid agents. Comparative studies indicate that it is similar to other products, which means that clinicians should consider the individual needs of each patient when selecting a long-term opioid to manage moderate to severe chronic pain associated with osteoarthritis. Physicians need to consider the risks and benefits of long-acting opioids in their osteoarthritis patients. Risk-benefit considerations include, but are not limited to, variability of patient response, potential drug–drug interactions, potential side effects, opioid rotation, and

### Limitations

The following points should be considered when identifying the appropriate patient for oxycodone CR therapy: (a) have they tried nonpharmacologic interventions?; (b) have they failed to respond or cannot tolerate nonopioid analgesics?; and (c) are immediate release opioids dosed every 4–6 hours around-the-clock being considered or might they benefit from every 12 hours dosing? If the patient is an appropriate candidate for long-acting oxycodone therapy, then the next step is to assess his or her pain, the historical level of pain, and any history of abuse. Therapy should be targeted at achieving optimal analgesia at the lowest effective dose.

### Conclusion

Clinical studies have demonstrated reasonable efficacy, safety, and tolerability of oxycodone CR when used to manage moderate to severe chronic osteoarthritis pain. The most common AEs are gastrointestinal and central nervous system related. These side effects might be more pronounced in elderly and debilitated patients. All patients need to be regularly assessed for the potential of abuse, misuse, and addiction, as well as the need for continued opioid therapy. Finally, it is important to incorporate a multimodal pain management regimen that includes nonpharmacologic and pharmacologic therapies when treating chronic osteoarthritis-related pain.
