Abstract: Hepatocellular carcinoma (HCC) is a common malignancy in developing countries and its incidence is on the rise in the developing world. The epidemiology of this cancer is unique since its risk factors, including hepatitis C and B, have been clearly established. The current trends in the shifting incidence of HCC in different regions of the world can be explained partly by the changing prevalence of hepatitis. Early detection offers the only hope for curative treatment for patients with HCC, hence effective screening strategies for high-risk patients is of utmost importance. Liver transplantation and surgical resection remains the cornerstone of curative treatment. But major advances in locoregional therapies and molecular-targeted therapies for the treatment of advanced HCC have occurred recently. In this review, current trends in the worldwide epidemiology, surveillance, diagnosis, standard treatments, and the emerging therapies for HCC are discussed.

Keywords: liver cancer, sorafenib, hepatitis C, TACE

Introduction

Hepatocellular carcinoma (HCC) is one of the leading causes of cancer-related deaths worldwide. More than 700,000 new cases are diagnosed each year throughout the world and also unfortunately more than 600,000 deaths are attributed to HCC each year.¹ Although the majority of the cases occur in Asia and Africa, the incidence has also been rising in the developed world. In the United States, the incidence has tripled over the last three decades with over 20,000 cases estimated to be diagnosed in 2011.¹ The geographical variation in the incidence of HCC is explained by disparity in the prevalence of the major risk factors such as hepatitis C virus (HCV) and hepatitis B virus (HBV) infection. In contrast to most malignancies, the predisposing conditions and major risk factors have been clearly defined for HCC. By recognizing the risk factors for HCC, high-risk groups can be identified and followed with screening strategies. Following high-risk patients with screening and surveillance has the real potential to detect HCC early and improve patient outcomes. When HCC is detected earlier, patients are candidates to receive curative treatments such as liver transplantation (LT), surgical resection, or ablation. In recent years, there have also been some major advances in the treatment of advanced HCC.

Epidemiology

Although HCC is the most common primary hepatic malignancy worldwide,¹ there are striking variations in its incidence in various parts of the world, with the major burden of disease falling on the developing world.² As per the GLOBOCAN report, 746,300

new cases of HCC were diagnosed worldwide in 2008 and HCC-related deaths in that year were reported to be 695,900 (Figure 1).² The high incidence to mortality ratio of 1.07 for HCC makes it the third most common cause of cancer-related deaths worldwide. The vast majority of this cancer burden was concentrated in the developing world which bore 84% of the total worldwide incidence and 83% of the total deaths. This distribution closely follows the global distribution of HBV and HCV infection, with the highest rates of HCC seen in those regions where these infections are endemic.^{3,4} Overall, HCC displays a male predominance, occurring two to four times more often in males than in females.⁵

There are some interesting trends in the global incidence of HCC. The cancer incidence in Asian countries like China and Korea has been shown to be on the decline in population-based studies.⁶ This recent decline is owed to increased vaccination against hepatitis B and preventive measures taken against aflatoxin.⁷ In contrast to the decreasing rates in Asian countries, the developing world has actually been experiencing an acceleration of HCC incidence, especially in the United States and Japan (Figure 2).^{8–11} The increase has been mainly attributed to the large number of young adults who acquired HCV infection through intravenous drug use and blood transfusions between the 1960s and 1980s. Further, the rising epidemic of obesity, diabetes, and nonalcoholic steatohepatitis (NASH) are also believed to contribute to the increase in HCC.¹² However, the overriding risk factor in 80%–90% of HCC cases regardless of etiology

is the presence of the preneoplastic cirrhotic liver.^{13,14} Based on current predictions, the incidence of HCC in the United States is projected to continue to increase over the next two to three decades.

Risk factors

Hepatitis B (HBV)

More than half of the world's HCC burden has been attributed to HBV infection.¹⁵ The International Agency for Research on Cancer in 1994 analyzed multiple cohort and case-control studies and reported that there was sufficient evidence in humans for the carcinogenicity of chronic HBV infection.¹⁶ The relative risk of HCC among people infected with HBV ranges from five to 49 in case-control studies and from seven to 98 in cohort studies.¹⁷ The etiopathogenesis of HBV-related HCC is complex and multiple pathways of carcinogenesis have been proposed. The process involves HBV causing chronic hepatic injury with cirrhosis and hepatocyte regeneration leading to accumulation of oncogenic mutations and also HBV DNA integration in the host genome causing transactivation of oncogenes of the host.^{18,19} While HBV can cause HCC in the absence of cirrhosis due to its ability to integrate into the host genome, the majority of the HBV-related cases occur in the background of cirrhosis.

The risk of HCC in patients with active chronic HBV infections is well established.^{20–22} But a recent study also showed that carriers of inactive chronic HBV are at risk for HCC and liver-related deaths.²³ In this study with a cohort of

around 20,000 patients, the hazard ratios were 4.6 for carriers of inactive HBV to develop HCC and 2.1 for liver-related deaths. Among patients with chronic HBV, there are additional risk factors that further increase the risk of HCC.^{24,25} Recently a nomogram has been introduced for the calculation of the risk of developing HCC based on risk factors such as: male gender, older age, family history of HCC, use of alcohol or tobacco, serum alanine aminotransferase level, coinfection with HCV, human immunodeficiency virus or hepatitis delta virus, persistent presence of hepatitis B e antigen, high serum levels of HBV DNA, HBV genotype C, and presence of cirrhosis.²⁶ These tools can be helpful for the clinician while counseling patients regarding preventive measures and potential strategies to decrease risk for HCC.

Hepatitis C (HCV)

The increase in the incidence of HCC in developed countries is closely linked to the epidemic of chronic HCV. While chronic HCV accounts for only around a third of HCC cases in developing countries, most of the HCC in developed countries is related to chronic HCV. For example, in Japan HCV accounts for 80%–90% of HCC cases, while in Italy and the United States it accounts for 40%–60% of HCC cases.^{27,28} Fortunately, the annual incidence of acute acquisition of HCV has been steadily declining in the United States since the early 1990s (Figure 3).^{29,30} The estimated risk of developing HCC in patients with chronic HCV has been reported as a wide range of odds ratio from 1.3 to 134,¹⁶ and a meta-analysis of 32 studies reported the risk to be increased 17-fold.³¹

Figure 3 Estimate of total new infections of hepatitis C in the United States. Based on the Centers for Disease Prevention and Control report from 1982–2008.³⁰
Abbreviation: HCV, hepatitis C virus.

The major risk factor for HCC in patients with chronic HCV is advanced hepatic fibrosis or cirrhosis.³² Unlike HBV, HCV is a ribonucleic acid virus and hence cannot integrate into the host genome. Similar to HBV, the carcinogenesis of HCV-associated HCC is thought to be a multistep process involving upregulation of inflammatory cytokines and induction of oxidative stress from chronic hepatitis, fibrosis, liver regeneration, and, ultimately, the development of cirrhosis.³³ These steps are likely shared by the risk factors that transform the liver parenchyma into the fibrotic nodules characteristic of cirrhosis, which sets the stage for dysplastic nodules and epigenetic and genetic changes resulting in the development of HCC. A number of risk factors can have a synergistic effect on the risk of HCC in patients with chronic HCV when present in combination. The association of HCV with the following risk factors has been shown to further increase the chances of developing HCC: alcohol use, coinfection with HBV or human immunodeficiency virus, diabetes mellitus, older age, African American race, thrombocytopenia, elevated alkaline phosphatase, esophageal varices, and smoking.^{33–36}

Nonalcoholic fatty liver disease (NAFLD)

NAFLD is being diagnosed with increasing frequency in the Western countries as a manifestation of the metabolic syndrome – obesity and diabetes mellitus type 2. The key process in NAFLD that predisposes patients to HCC is the development of NASH. The diagnosis of NASH relies on a biopsy with a histopathology showing features of steatosis, hepatocellular injury (ballooning, Mallory bodies), and fibrosis.³⁷ The presence of NASH places patients at risk for progressive fibrosis and subsequent cirrhosis. The pathophysiology of hepatic carcinogenesis in patients with NAFLD-NASH has not been completely elucidated.³⁸ But initial investigations suggest that excess fatty acid supply and hepatocellular steatosis elicit increased fatty acid oxidation with consecutively enhanced reactive oxidative stress.³⁹ This process further promotes proinflammatory cytokine release, prooncogenic signals, and epigenetic changes. Importantly, these cascades of events may take place in the absence of cirrhosis. In fact, case reports have been published where HCC arose in patients with NASH in the absence of cirrhosis.⁴⁰

Most of the data that examines the cause–effect relationship between NASH and HCC are population-based cohort and case-control studies. In general, these studies support the link between NAFLD and HCC by showing that patients who are obese and have diabetes mellitus type 2 are twice as likely to develop HCC compared to non-obese and nondiabetic patients.^{41–44} In a recent prospective study from the Cleveland

clinic, the yearly cumulative incidence of HCC in patients with NASH was found to be similar to that associated with HCV infection – 2.6% in patients with NASH-cirrhosis compared with 4% in patients with HCV cirrhosis.⁴⁵ NAFLD-NASH is an emerging risk factor for HCC with the potential to contribute and eventually overtake HCV as the main risk factor for HCC given the galloping rates of obesity and diabetes in the developed world. Efforts should continue to better understand the implications and risks of NAFLD-NASH for HCC.

Other risk factors

In Asia and Africa, exposure to dietary aflatoxin is an important risk factor for the observed high rate of HCC. Aflatoxin is well known to be both an independent risk factor for HCC and act as a cofactor in chronic HBV infection.⁴⁶ In sub-Saharan Africa, human immunodeficiency virus infection is recognized as a frequent cofactor that increases the risk of HCC in patients with chronic HBV or HCV infection.⁴⁷ Another contributable risk factor is tobacco use, which is being identified with increasing frequency in epidemiological studies. In addition, as the vast majority of cases of HCC arise in the setting of cirrhosis, less common causes of cirrhosis such as autoimmune hepatitis, alpha-1 antitrypsin deficiency, or hereditary hemochromatosis increase the risk of the development of HCC. Figure 4 shows the major factors associated with cirrhosis and HCC.

Prevention

Antiviral treatment

The main preventive strategy for the development of HCC in chronic HBV and HCV infection is treatment with antiviral therapy. One large, randomized double blind controlled trial in Chinese patients with hepatitis B e antigen positive chronic HBV infection with high serum levels of HBV DNA and advanced fibrosis showed that compared to patients treated with placebo, patients treated with lamivudine had less disease progression and incidence of HCC.⁴⁸ A pooled analysis of several nonrandomized studies of interferon-treated patients with HCV showed a significant reduction in the incidence of HCC in patients who achieve viral eradication with treatment compared with nonresponders.⁴⁹ The lower incidence of HCC is also observed in patients with HCV cirrhosis who achieve viral eradication after antiviral therapy.⁵⁰ However, while achievement of a sustained virologic response lowers the risk for HCC, it does not eliminate the risk of HCC in HCV-related cirrhosis. These findings certainly suggest that patients with cirrhosis should continue surveillance because the risk of occurrence of HCC was

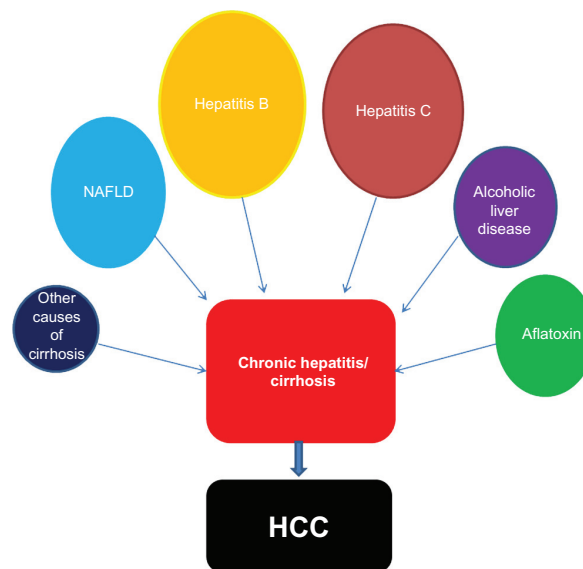

Figure 4 Risk factors for developing hepatocellular carcinoma.

Abbreviations: HCC, hepatocellular carcinoma; NAFLD, nonalcoholic fatty liver disease.

not entirely avoided. Long term antiviral (maintenance) therapy in patients with HCV cirrhosis, who did not have a sustained response to initial antiviral therapy, did not significantly reduce the risk of HCC after a short follow-up of 4 years.⁵¹ A more recent analysis of this Hepatitis C Antiviral Long-term Treatment against Cirrhosis (HALT-C) cohort providing extended follow-up (6 years) showed that maintenance interferon therapy did lower the risk of HCC among patients with cirrhosis, but not advanced fibrosis.⁵² Most of the studies in viral hepatitis show that antiviral therapies for chronic HBV and HCV infection can prevent HCC, but do not completely eliminate risk of developing HCC.⁵³

Caffeine intake, particularly in the form of coffee, deserves discussion since several observational studies have demonstrated a hepatoprotective effect by showing that coffee drinking is associated with a reduced risk of HCC.⁵⁴ While the mechanisms of this action and the exact amount of coffee consumption necessary to obtain a benefit are unclear, research in this area is ongoing.

Surveillance

All patients at high risk of developing HCC are recommended by the practice guidelines from the American Association of the Study of Liver Diseases (AASLD) to be enrolled in formal surveillance.⁵⁵ Surveillance is considered cost-effective when the annual incidence of HCC in a population is greater than 1.5% per year. The groups of patients for whom surveillance is indicated are listed in Table 1. In general, surveillance is recommended for all patients with

cirrhosis regardless of cause and for HBV carriers without cirrhosis if they are Africans older than 20 years of age, Asians older than 40 years of age, or if they have a family history of HCC. The goal of surveillance is to detect HCC early so curative treatments can be applied with improved outcomes. The surveillance strategy recommended is an ultrasound (US) of the liver every 6 months. The use of US as the primary means of surveillance for HCC in at-risk populations has long been recommended in clinical guidelines. US has the advantage of being noninvasive and inexpensive, but operator experience is a crucial factor in overall sensitivity.⁵⁶ Systemic reviews evaluating standard US alone demonstrate a range of sensitivity for HCC from 30%–70%.^{57,58} On US, HCC lesions will typically appear as hypoechoic lesions.⁵⁹

There are many studies which examined the efficacy of surveillance in early detection and also in improving

Table 1 Groups for whom surveillance for hepatocellular carcinoma is recommended by the 2010 American Association of the Study of Liver Diseases practice guidelines

Cirrhosis secondary to:	Chronic hepatitis B carriers without cirrhosis:
Viral hepatitis (B, C)	Asian male over age 40
Primary biliary cirrhosis	Asian female over age 50
Genetic hemochromatosis	African over age 20
Alpha 1-antitrypsin deficiency	Family history of hepatocellular carcinoma

survival, which are the ultimate goals of any population-based screening strategy. However, robust evidence in support for screening is lacking since it would be unethical to randomize at-risk patients into screened and nonscreened groups in order to compare outcomes. The best level of evidence comes from one randomized controlled trial involving the Chinese population with chronic hepatitis B using abdominal US and alpha-fetoprotein (AFP) every 6 months, showing a reduction in mortality with this screening strategy.⁶⁰ Additional evidence in support of surveillance showing a survival benefit comes from observational studies.^{61,62} From these studies it is accepted that earlier detection of HCC does improve survival and that it is cost-effective. But despite several guidelines emphasizing the importance of screening it has been shown that only a small percentage of patients with cirrhosis actually undergo periodic surveillance. In a recent population-based cohort identified from the linked Surveillance, Epidemiology, and End Results registry–Medicare databases, less than 20% of patients who developed HCC had received regular surveillance.⁶³

In the updated practice guidelines by the AASLD for HCC, obtaining the AFP serum level was not recommended as a screening test due to its inadequate sensitivity. In a systematic review of literature, when AFP > 20 mcg/L is used as a cutoff, the sensitivity of detecting early HCC is reported to be 25%–65% and specificity to be 80%–94%.⁶⁴ The low sensitivity makes the use of AFP as the sole screening strategy less desirable. But the largest randomized controlled trial which showed improved survival with surveillance did use AFP as an adjunct with US for screening. Though the AASLD practice guidelines have excluded AFP from their recommendation, the European Association for the Study of the Liver did recommend the use of US with AFP for surveillance.⁶⁵ In the background of existing inadequacies in screening practices, complete exclusion of AFP – an easily available cost-effective tool – is considered controversial.^{66,67} Other serum markers for HCC, such as *Lens culinaris* agglutinin-reactive AFP (AFP L3), des-gamma carboxyprothrombin, glypican 3, human hepatocyte growth factor, and insulin-like growth factor, garnered initial interest, but require more robust confirmatory studies since studies show them to provide limited use as a sole screening strategy when compared with AFP alone.^{68,69}

Diagnosis

HCC can be diagnosed by noninvasive imaging using its unique dynamic behavior on contrast-enhanced computerized tomography (CT) or magnetic resonance imaging

(MRI). The typical vascular profile of HCC on dynamic imaging is early arterial phase enhancement followed by loss of enhancement in the portal venous and delayed phases compared to the rest of the liver. This imaging characteristic lends itself to the diagnosis of HCC with a sensitivity of 90% and specificity of 95%.⁷⁰

US

Another imaging option to diagnose HCC once a hepatic nodule is detected on standard US may include contrast-enhanced US. Efforts to improve the sensitivity of standard US have evolved into a medium known as phase-inversion harmonic contrast-enhanced imaging, which utilizes microbubble contrast agents. The use of the contrast medium allows microflow imaging, which demonstrates the vascularity of the lesions in great detail.⁷¹ HCC lesions are typically characterized by arterial hyperenhancement, with hypoenhancement in the portal venous and delayed phases, similar to CT and MRI.⁷² A large multicenter study of over 1300 patients with liver tumors demonstrated a diagnostic accuracy of 85% for HCC with modern contrast-enhanced US.⁷³ A subsequent prospective study of 317 patients with hepatic masses showed that contrast-enhanced US had a sensitivity of 90%, a specificity of 99%, and a diagnostic accuracy of 89%.⁷⁴ However, recent studies have raised concern over this technology because of its inability to adequately differentiate cholangiocarcinoma from HCC, causing a false positive HCC diagnosis in patients with cholangiocarcinoma. Thus, contrast-enhanced US it is not recommended by the AASLD practice guidelines as a diagnostic technique.

CT

CT is the modality used in most centers to make the radiological diagnosis of HCC after a liver nodule is detected on US. Most centers conduct a four-phase multidetector CT (MDCT) scan, which consists of a non-enhanced phase, an arterial phase (which occurs 20–30 seconds after contrast injection), a portal venous phase (which occurs 65–80 seconds after contrast injection), and a delayed phase. On the four-phase CT, HCC will classically appear as a hyperattenuated lesion in the arterial phase, with loss of enhancement termed rapid washout in the portal venous and/or delayed phase. CT has fairly high specificity but variable sensitivity for detecting HCC. A systematic review found that traditional spiral CT had a specificity of 93% but a sensitivity of only 68% in diagnosing HCC. A subsequent review of the performance of the newer 64-slice MDCT technology versus spiral CT showed improved sensitivity (65%–79% compared to 37%–54%) with specificity

maintained above 90%.⁷⁵ However, sensitivity continues to be a challenge for small lesions dropping to 33%–45%, particularly for those less than 1 cm.

MRI

MRI is an appealing imaging modality since it does not use ionizing radiation. Instead, MRI uses magnetic fields to induce and detect a signal that allows greater differentiation between neoplastic tissue and normal liver parenchyma even without the use of contrast media, making it an attractive option for the diagnosis and staging of HCC.⁷⁶ Traditional dynamic contrast-enhanced MRI of the liver is performed using gadolinium chelates. In gadolinium-enhanced MRI, the typical HCC lesion has hyperintense signal intensity on T1-weighted images during the arterial phase and rapid washout during portal venous and delayed phases.^{77–79} Standard gadolinium-enhanced MRI has a sensitivity of at least 90% and a specificity of at least 95% for the detection of HCC for tumors greater than 2 cm in diameter.⁸⁰ The majority of the studies show dynamic MRI to be superior to CT for detecting HCC lesions.^{81,82} However, as with the other imaging modalities discussed above, the sensitivity of standard MRI decreases for HCC lesions smaller than 2 cm, where it can be as low as 30%.^{83,84}

Recently, targeted contrast agents have been developed in an effort to improve the sensitivity of MRI for HCC. These include the “dual contrast” agents gadolinium-ethoxybenzyl-diethylenetriaminepentaacetic acid (Primovist® and Eovist® in Europe and the United States, respectively) and gadobenate dimeglumine (Gd-BOPTA/Dimeg, MultiHance®). These agents serve both as markers of hepatobiliary excretion and vascularization. Typical HCC lesions imaged with these contrast agents will not display uptake, unlike benign nodules on the delayed hepatobiliary phase.⁸⁵ While it appears that gadolinium-ethoxybenzyl-diethylenetriaminepentaacetic acid-enhanced MRI performs similarly to MDCT for diagnosis of HCC lesions larger than 2 cm in diameter, enhanced MRI might be slightly more sensitive than MDCT for lesions smaller than 1 cm in diameter (with a trend towards statistical significance).⁸⁶

Nuclear imaging

In general, HCC has low fluorodeoxyglucose avidity in positron emission tomography due to the variable uptake of fluorodeoxyglucose, which is dependent on the differentiation of tumor. Typically, poorly- to moderately-differentiated tumors light up on positron emission tomography scans. The sensitivity of positron emission tomography for detecting HCC can be 40%–50%, and this poor sensitivity is why it is not recommended as

a screening tool.⁸⁷ Recently, the alternative tracer of C11-acetate has been introduced to improve the ability to visualize HCC.⁸⁸ While well-differentiated HCC demonstrates negative fluorodeoxyglucose uptake and positive 11C-acetate uptake, poorly-differentiated HCC displays the reverse characteristics. The combined use of fluorodeoxyglucose and C11-acetate in HCC has been proposed as a strategy to improve detection on nuclear imaging. However, other studies show that even with the combination of tracers the sensitivity for detecting small HCC remains poor.⁸⁹ Further studies are needed to better define the role of nuclear imaging in patients with HCC.

Diagnostic algorithm

The most recent AASLD practice guidelines updated the diagnostic algorithm for HCC in patients with cirrhosis who have hepatic nodules detected on surveillance US imaging (Figure 5). The diagnostic approach depends on the size of the nodule and can involve a sequence of events such as repeat imaging and biopsy. The diagnosis is heavily based on a single dynamic imaging technique showing intense arterial uptake followed by loss on enhancement or “washout.” This typical imaging characteristic of HCC has been validated and shown diagnostic accuracy with a single imaging technique.^{90,91,99} The nodules that are less than 1 cm have a low likelihood of being HCC and are recommended to be followed with imaging every 3 months in order to detect growth suggestive of malignant transformation. The absence of growth during a monitoring period between 1–2 years implies a low likelihood of HCC, while enlargement over this period suggests malignancy and warrants further investigation. For nodules larger than 1 cm it is recommended to evaluate with either a four-phase MDCT or dynamic MRI. If the greater than 1-cm lesion displays the typical HCC dynamic features, then the lesion is diagnosed and treated as HCC. If the vascular profile is not typical, then a second sequential contrast enhanced imaging (MRI or MDCT) study is performed. If both the arterial hypervascularity and washout are seen on the second imaging study, then the diagnosis of HCC is made. If the lesion appears atypical for HCC on this sequential imaging study, then image-guided core biopsy should be considered. However, biopsies of small tumors less than 2 cm can yield false negative rates as high as 30%–40% and the small size of the lesions can be difficult to target. Further, biopsies can be associated with a risk of tumor seeding along the needle track, but a recent review reports this occurrence is low (2.7%).⁹² Interpretation of biopsies is challenging, particularly when trying to differentiate between high-grade dysplastic nodules and HCC. For this reason, the guidelines highly encourage

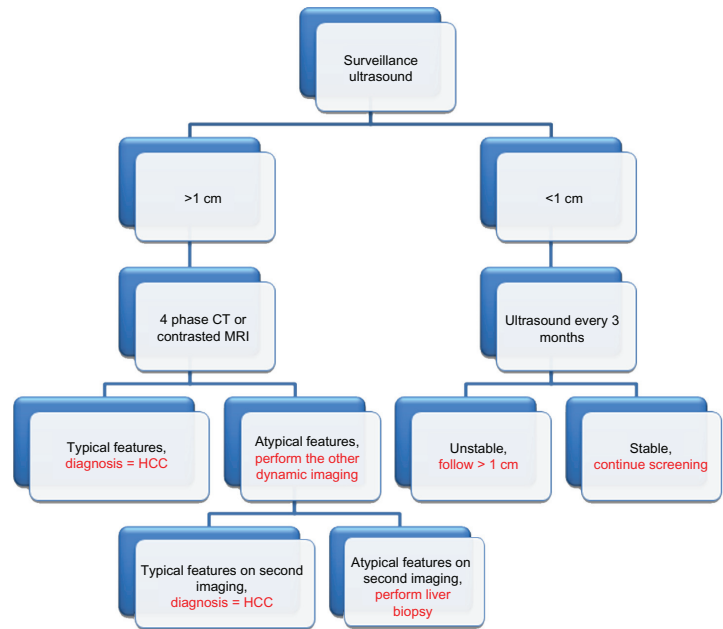

Figure 5 Diagnostic algorithm to diagnose hepatocellular carcinoma as recommended by the American Association of the Study of Liver Diseases 2010 practice guidelines. **Notes:** Copyright © 2005. expert pathology review by reinforcing the use of immunostains for glypican 3, heat shock protein 70, and glutamine synthetase since positivity for two of these three stains confirms HCC.⁹³ The recommended sequential approach with dynamic imaging studies in the algorithm decreases the number of potential biopsies but emphasizes the importance of strict adherence to diagnostic imaging protocols.

Staging

While several staging systems for HCC exist, the Barcelona Clinic Liver Cancer (BCLC) staging and prognostic system has emerged as the most widely accepted in clinical practice as it incorporates tumor stage, cirrhosis stage, and functional performance status (PS), and links stage with a treatment algorithm (Table 2).⁹⁴ Further, this staging system is endorsed by both American and European liver societies and has been independently validated in European and American cohorts.^{95,96} BCLC identifies several stages of HCC, each of which is associated with a different prognosis and treatment recommendation based on the impact of treatment on survival.

Very early stage HCC (stage 0) has the best prognosis, but is unfortunately the hardest to diagnose, as it presents with one lesion smaller than 2 cm in diameter. Patients in this stage have stable cirrhosis (Child–Pugh class A), and the tumor displays no evidence of vascular invasion. Patients with early

stage HCC (stage A) present with either a solitary lesion or up to three lesions each up to 3 cm in diameter. These patients have preserved liver function (Child–Pugh class A or B) and reasonable functional status (PS 0–2). Patients with stage A HCC can expect 5-year survival rates of 50%–75%, with the choice of treatment dictated by the presence or absence

Table 2 The Barcelona Clinic Liver Cancer staging system for hepatocellular carcinoma

	Performance status	Tumor burden	Liver function
Stage A (early)			
A1	0	Single, <5 cm	No PHT
A2	0	Single, <5 cm	PHT, normal bili
A3	0	Single, <5 cm	PHT, elevated bili
A4	0	Up to 3, <3 cm	Child–Pugh class A–B
Stage B (intermediate)	0	Large multinodular	Child–Pugh class A–B
Stage C (advanced)	1–2	Vascular invasion or extrahepatic disease	Child–Pugh class A–B
Stage D (end stage)	3–4	Any	Child–Pugh class C

Notes: Copyright © 2005. Reprinted with permission from John Wiley and Sons. Bruix J, Sherman M. Management of hepatocellular carcinoma. *Hepatology*. 2005;42(5):1208–1236. Updated July 2010. Accessed February 20, 2012.⁵⁵ **Abbreviations:** PHT, portal hypertension; bili, total bilirubin.

of portal hypertension, the degree of liver dysfunction, and other medical comorbidities.

Intermediate stage HCC (stage B) presents as multinodular HCC, but these patients continue to display preserved liver function (Child–Pugh class A or B) and good functional status (PS 0), and have no cancer-related symptoms or evidence of vascular invasion. Transarterial therapy confers a survival benefit to patients with stage B HCC. Patients with evidence of vascular invasion or extrahepatic spread have advanced stage HCC (stage C). These patients typically have some compromise of functional status (PS 1 or 2) due to HCC, and do receive a survival benefit from treatment with sorafenib.

Patients with terminal stage HCC (stage D) present with decompensated cirrhosis (Child–Pugh class C), poor functional status (PS > 2), and advanced tumor growth (vascular invasion and/or extrahepatic spread). Unfortunately, these patients receive no benefit from the currently available therapies, and survival with symptomatic treatment is around 3 months.

Treatment

As mentioned above, there are multiple therapeutic modalities available for HCC, and the selection of a particular therapy depends on the stage of HCC, the degree of underlying liver synthetic function, other medical comorbidities, and the availability of the treatment modality and local clinical expertise. These decisions are best made by a multidisciplinary team consisting of hepatologists, surgeons, diagnostic and interventional radiologists, oncologists, and pathologists.

Surgical resection

Surgical resection represents one potentially curative treatment option for carefully selected patients. It is the ideal treatment for patients with small, solitary nodules without underlying cirrhosis, but this clinical situation is present in less than 5% of cases.⁹⁷ Most patients with HCC have underlying cirrhosis and require careful evaluation for resection because of the potential for postresection hepatic decompensation. The best candidates for resection are patients with stage 0 or A HCC with Child–Pugh class A cirrhosis characterized by normal portal pressures (hepatic venous pressure gradient <10 mmHg) and normal bilirubin (total bilirubin <1 mg/dL).⁹⁷ In these patients with normal bilirubin and the absence of clinically significant portal hypertension (lack of esophageal varices and splenomegaly with less than 100,000 platelets or hepatic venous pressure gradient is under 10 mmHg), there is minimal risk of postoperative liver

failure and they achieve a 5-year survival of 70% compared to 30% for those with a bilirubin of more than 1 mg/dL and portal hypertension.⁹⁸ Interestingly, a Japanese study by Ishizawa et al concluded that resection can provide survival benefits for patients with multiple tumors in a background of Child–Pugh class A cirrhosis and also for patients with portal hypertension.⁹⁹ But there is no consensus yet on extending resection to these patients.¹⁰⁰ The minimal critical size of the future liver remnant after resection to avoid postresection liver failure is 25% in the presence of a normal liver and 50% in patients with cirrhosis.¹⁰¹ When the anticipated future liver remnant volume is below these criteria, ipsilateral portal vein embolization is often utilized to increase the volume of the future remnant and increase the safety of the resection.¹⁰²

Unfortunately, after resection the majority of patients develop recurrence with most series reporting 5-year recurrence rates exceeding 70%.^{103,104} If the tumor recurs and the tumor burden is within the Milan criteria, then salvage LT is being reported as a potential therapeutic strategy.^{105,106} Presently, there is a lack of effective adjuvant therapies to prevent recurrence after resection. Several approaches have failed when taken into larger trials, such as the use of retinoid and vitamin K2.¹⁰⁷ Results from the Phase III randomized trial comparing sorafenib to placebo as an adjuvant therapy after resection or ablation (STORM [Sorafenib as Adjuvant Treatment in the Prevention of Recurrence of HCC] trial) to prevent recurrence is eagerly awaited since it has completed enrollment. Another Phase III study is planned using an inhibitor of the enzyme heparanase involved in metastasis (PI-88) after showing promising results in a Phase II study.¹⁰⁸

Transplantation

LT is another curative option for patients with HCC. For patients with decompensated cirrhosis (Child–Pugh B and C cirrhosis), LT is the most viable treatment option since they can't undergo resection due to marginal liver function. The initial experiences with LT for HCC were dismal with high posttransplant recurrence rates and poor 5-year survival due to poor patient selection. The seminal study published by Mazzaferro et al in 1996 established the tumor burden best handled with LT.¹⁰⁹ This study showed that patients with tumors confined to the liver within the Milan criteria – defined as having one lesion ≤5 cm or up to three lesions ≤3 cm in diameter, a 5-year survival rate of >70%, and a low tumor recurrence rate of <15% – are the best LT candidates. This degree of tumor burden is compatible with early stage HCC using the BCLC staging system, and LT is now widely accepted as a standard treatment for this stage

of disease. In general, LT is seen as superior to resection since transplantation has much lower rates of recurrence, which is the main cause of long-term death in resection, and since it treats both the HCC and cirrhosis.

Currently, the United Network for Organ Sharing uses the Model for End-stage Liver Disease (MELD) score to stratify patients based on their risk for short-term mortality, and those with higher scores get transplanted earlier. Since patients with HCC are at higher risk of succumbing to tumor progression than to sequela of cirrhosis, they are assigned a higher MELD score based on the radiologic diagnosis of HCC within the Milan criteria to facilitate earlier transplant. Initially patients with HCC received a score of 22 for T1 HCC and 29 for T2 HCC. But after studying the outcomes and perceived unfair advantage of this higher score, modification has now been made: no MELD exception points for T1 and 22 for T2.¹¹⁰ For each 3-month period in which the patient remains on the waiting list, three additional MELD points are awarded based on the expected 10% increase in pretransplant mortality while on the waiting list.

Since HCC can progress while patients are on the transplant list, locoregional bridging therapies such as chemoembolization and radiofrequency ablation (RFA) are routinely employed to maintain the tumor burden within Milan criteria and prevent dropout on the waiting list. Several studies, including one from the authors' center, have not demonstrated a survival benefit in employing these interventions.^{111–113} But other studies have suggested the efficacy of pretransplant locoregional therapy in preventing progression and decreasing dropout rates from the transplant list.^{114,115} Current guidelines recommend the use of locoregional therapy for bridging to transplant only if the anticipated time on the waiting list is longer than 6 months.¹¹⁶ In order to determine if a true oncologic benefit exists with the use of these interventions, adequately designed and prospective randomized studies are needed.

For those beyond the United Network for Organ Sharing criteria, downstaging the size and numbers of HCC lesions with one or a combination of locoregional treatments can be a successful strategy in close to half of patients, as shown by the University of California at San Francisco protocol.¹¹⁷ However, the safety of expanding the Milan criteria has not been established and overall there is no current consensus on the expansion of criteria for transplant eligibility.

Locoregional therapy

In patients with early stage HCC who are not eligible for resection or transplantation, several forms of locoregional

therapy, such as RFA, percutaneous alcohol injection (PEI), cryoablation, and transarterial therapies, can be used.

RFA and PEI

The two most commonly used techniques to ablate early stage HCC are RFA and PEI. PEI causes coagulation necrosis of tumors by cellular dehydration, thereby achieving complete tumor necrosis in 90%–100% of the HCC tumors less than 2 cm, 70%–80% of the HCC tumors between 2–3 cm, and 50% in HCC tumors between 3–5 cm.^{118,119} PEI is popular due to its low rate of adverse events and being an inexpensive procedure. The major drawback is its high local recurrence rate which requires repeated injections particularly for lesions larger than 3 cm since the ethanol can't access the entire tumor volume. RFA causes thermal necrosis to tumors by delivering electromagnetic energy through single or multiple needle electrodes inducing a wider region of complete tumor necrosis, and because of this has largely replaced PEI. The decision regarding which technique to employ is usually based on tumor size, tumor location, presence of portal vein thrombus, and local expertise. For small tumors, RFA has been shown to be more efficacious than PEI in a meta-analysis and also in a randomized trial in terms of local disease control, less operator variability, less local recurrence (8%–14% versus 22%–34%), and overall survival (100% and 98% versus 96% and 88% for 1 year and 2 years, respectively).^{120,121} RFA is the preferred ablative technique for patients with small tumors located away from major vessels and diaphragm. Hence, RFA is currently the first-line therapy employed in this patient group. However, RFA can be associated with pain, intraperitoneal bleeding, tumor seeding, hepatic abscess formation, bile duct injury, and hepatic decompensation. Further, RFA also has limitations in terms of tumor location where it may be contraindicated in certain areas of the liver due to the potential damage to adjacent tissues and loss of efficacy due to large blood vessels causing the heat-sink phenomena. For these reasons, PEI can still be used for small tumors.

Newer ablative techniques are also being investigated. One new technique for local ablation is using microwave technology to induce an ultra-high-speed alternating electric field.¹²² Irreversible electroporation (NanoKnife® System; AngioDynamics, Latham, NY) is another ablation technique in which microsecond to millisecond electrical pulses are delivered to the tumor leading to necrosis through irreversible cell membrane permeabilization.¹²³ The advantages of this technique over RFA include its potential to spare adjacent vasculature, lack of detrimental effects on surrounding architecture, and the ability to control and monitor the affected

area with electrical impedance tomography.¹²³ The safety and efficacy of irreversible electroporation is being investigated in a multicenter European prospective pilot trial for the treatment of early stage HCC and has recently completed enrollment.¹²⁴ A third strategy being investigated to improve the efficacy of RFA is ThermoDox®. This drug delivery method uses a temperature-sensitive version of liposomal doxorubicin, which after intravenous administration rapidly releases the drug at the tumor site being heated with RFA leading to enhanced necrosis.¹²⁵ These novel techniques for tumor ablation can overcome the limitations of RFA, and further studies are highly awaited to determine their potential applicability and incorporation into current treatment paradigms for early HCC.

Transarterial therapies

For patients presenting with intermediate stage HCC, transarterial chemoembolization (TACE) is the standard clinical treatment. The dual blood supply of the liver and arterialization of HCC allows the administration of chemotherapeutic and embolizing agents selectively into the artery supplying the tumor. Two randomized controlled trials demonstrated the clinical benefit of TACE over symptomatic supportive care in select patients with unresectable, multifocal HCC with adequate liver function. One randomized study included predominantly patients with HCV-related cirrhosis and showed a survival advantage for TACE at 1 year (82%) and 2 years (63%) compared to controls at 1 year (63%) and 2 years (27%).¹²⁶ The second randomized study included mostly HBV patients and also showed significantly better survival for TACE at 1 year (57%), 2 years (31%), and 3 years (26%) compared to controls at 1 year (32%), 2 years (11%), and 3 years (3%).¹²⁷ These two studies and a subsequent meta-analysis show TACE improved 3-year survival rates from 10% to 40%–50% and median survival from 16 to 20 months. These results established TACE as the standard of care for asymptomatic patients with multinodular HCC with no vascular invasion and with Child–Pugh class A cirrhosis.¹²⁸ For patients with more symptomatic disease with impaired liver function compatible with Child–Pugh B or C disease or portal vein thrombosis, TACE is not an optimal technique and contraindicated. However, some series report a similar treatment-related benefit in HCC patients with portal vein thrombosis using highly selective TACE.¹²⁹ The most common complication in patients treated with TACE is a postembolization syndrome occurring in more than 50% of patients. Postembolization syndrome consists of transient fever, abdominal pain, nausea, ileus, and elevated alanine aminotransferase. This syndrome is usually self-limited with

supportive care, typically lasting between 24–48 hrs. Hepatic decompensation in the form of ascites and gastrointestinal bleeding is the most feared complication occurring in less than 10% of patients. Additional treatment-related side effects from the chemotherapy are nausea, vomiting, bone marrow suppression, alopecia, and, potentially, renal failure.

TACE is now the most widely performed palliative treatment for intermediate stage HCC. The studies establishing TACE as the first-line treatment for locally advanced HCC used selective injection of chemotherapeutic agents along with an oily carrier such as lipiodol into the feeding arteries of the tumor to obtain higher and prolonged local drug concentrations.¹³⁰ An embolic material was then injected that caused ischemia and necrosis. A wide range of side effects have been reported in the literature with this technique such as post-TACE syndrome, intrahepatic biloma, acute hepatic failure, liver infarction, abscess formation, and chemotherapy-related systemic toxicities.¹³¹ In addition, when TACE is applied in clinical practice, a number of variables exist that contribute to the heterogeneous nature of the technique, such as the type of anticancer drugs (eg, doxorubicin, cisplatin, or epirubicin) and dose, the choice of embolic agent (eg, gelfoam, polyvinyl alcohol, or microspheres), delivery, timing, selectivity, the treatment schedule (on demand based on residual tumor or fixed schedule), and whether embolization is done to complete or near stasis.¹³²

More centers are now using the recently developed doxorubicin-loaded drug-eluting beads TACE (DEB-TACE) (DC Bead®; Biocompatibles UK Ltd, Farnham, UK) since delivery with this strategy increases the intratumoral delivery of cytotoxic drugs in a predictable manner that limits systemic adverse events.^{133,134} DEB-TACE minimizes a number of variables inherent with conventional, lipiodol-based TACE technique by using a uniform size of beads with predefined doses of chemotherapy. The beads absorb a predictable concentration of the chemotherapy and upon reaching the tumor vascular bed slowly release the drug in a controlled fashion. The simultaneous release of drug with induction of ischemia as the beads embolize the tumor allows the technique to be performed in a more consistent and reproducible manner.

DEB-TACE was directly compared with conventional, lipiodol-based TACE in a randomized Phase II trial for safety and efficacy.¹³⁵ The DEB-TACE group showed higher rates of complete response, objective response, and disease control compared with the conventional TACE group. However, these differences in the 6-month tumor response (DEB-TACE 63% versus conventional TACE 52%; $P = 0.11$) was not significant. The use of DEB-TACE was associated with improved

tolerability marked by significant reduction in doxorubicin-related side effects and serious liver toxicity. Further, the patients with more advanced features, such as Child–Pugh B cirrhosis, worse PS, and bilobar disease, demonstrated significantly higher tumor response rates with DEB-TACE with improved safety. These findings suggest the DEB-TACE may be used safely in Child–Pugh B cirrhosis which is presently a contraindication for TACE in the AASLD HCC practice guidelines. The association of DEB-TACE with an increase in tumor response and a reduction in both liver and systemic side effects has led to its rapid use at referral centers. Newer modes of transarterial drug delivery are also being developed. An example is the hepaspheres (HepaSphere™ Microspheres; Merit Medical Systems Inc, South Jordan, UT), which are superabsorbent polymer microspheres undergoing early stage evaluation.¹³⁶

Transarterial brachytherapy or radioembolization is another palliative treatment for intermediate stage HCC. Radioembolization involves hepatic arterial injection of yttrium-90 microspheres (Y-90) as glass (TheraSphere®; Nordion, ON, Canada) or resin (SIR-Spheres®; Sirtex Medical, Sydney, Australia). The Y-90 particles are smaller in size than the drug-eluting beads used for TACE. Their smaller size allows them to be preferentially trapped at the capillary bed leading to less tumor ischemia and angioneogenesis. Once they obstruct in the tumor capillary bed, then the Y-90 particles can deliver up to 150 Gy of beta radiation to induce tumor necrosis by radiation and microscopic embolization.¹³⁷ Radiation exposure is limited to adjacent healthy tissue given its radius of action of up to 1 cm and half-life of 62 hours. The reported literature on Y-90 has been largely from uncontrolled single center experiences.¹³⁸ This American cohort experience used Y-90 glass microspheres and reported survival that differed significantly by the dual competing risks of HCC stage and Child–Pugh status. In this series, patients with Child–Pugh class A cirrhosis and intermediate stage HCC benefited the most with a median survival of 17.2 months, while patients with Child–Pugh class B cirrhosis had the worse outcomes with a median survival of 7.7 months. The largest clinical experience comes from the European Network using the Y-90 glass microspheres and reported a median survival in intermediate stage HCC of 16.9 months and advanced stage HCC of 10 months.¹³⁹ At the present time, Y-90 treatment has not been evaluated in controlled trials directly comparing Y-90 to TACE treatment. Comparison is limited to retrospective studies, one evaluating Y-90 to conventional lipiodol-based TACE that showed statistically similar survival (20.5 months with Y-90 versus 17.4 months

with TACE, $P = 0.23$).¹⁴⁰ While a direct comparison in a randomized trial is needed, the number of patients needed (more than 1000) based on power calculation to compare both treatments in intermediate stage HCC is a significant barrier. Further evaluation of Y-90 in combination with other agents such as sorafenib seems more reasonable.

Combination TACE and sorafenib

Chemoembolization results in tumor ischemia and hypoxia which increase pro-angiogenic growth factors such as vascular endothelial growth factor (VEGF).¹⁴¹ VEGF can induce angiogenesis in the peripheral parts of the tumor thereby offsetting the desired antitumor effects of TACE. Since angiogenesis plays a major role in the pathogenesis of HCC, the combination of TACE and angiogenesis inhibitors like sorafenib for intermediate stage HCC has strong rationale. A number of combination strategies are under investigation. One approach shown to be safe and tolerable in early studies is maintaining continuous dosing of sorafenib without stopping as the patients undergo TACE.¹⁴² The authors' center has examined the safety, tolerance, and efficacy of combining TACE and sorafenib with a protocol that uses concomitant DEB-TACE and sorafenib.¹⁴³ The results showed the combination of TACE and sorafenib is tolerable but is associated with a higher rate of adverse events. The adverse events are similar to the side effect profile observed with sorafenib monotherapy. In addition, the combination did not adversely impact the ability to perform TACE. The combination yielded encouraging efficacy with a disease control rate of 68% and overall median survival of 18.5 months given that 20% of the 47 patients had stage C HCC and Child–Pugh class B cirrhosis. Currently, this combination of TACE and sorafenib is undergoing evaluation as part of a multinational, randomized, placebo-controlled trial comparing TACE plus placebo versus TACE plus sorafenib for intermediate stage HCC with Child–Pugh class A cirrhosis (SPACE [Sorafenib or Placebo in Combination with TACE for Intermediate-Stage HCC] study). The study recently completed enrollment and results are anticipated soon. If the randomized design confirms a benefit to the combination of TACE and sorafenib and tolerability, then this approach can be incorporated into clinical practice.

Sorafenib

Sorafenib is an oral multikinase/tyrosine kinase inhibitor that has shown a survival benefit over best supportive care in two pivotal studies (SHARP [A Phase III Study of Sorafenib in Patients with Advanced HCC] and Asian

Pacific trials) in patients with Child–Pugh class A cirrhosis and advanced HCC compatible with stage C by the BCLC system.^{144,145} Single agent sorafenib for advanced HCC provided a modest benefit with a median improvement in overall survival for sorafenib over placebo of about 3 months. Further, treatment largely stabilized the tumor by delaying progression, reflecting how targeted agents act predominantly through cytostatic pathways. The efficacy of sorafenib in these trials led to its approval by regulatory agencies as the first systemic treatment in advanced HCC and the endorsement of sorafenib as the standard of care for this stage by practice guidelines. The proven benefit of sorafenib has been a major milestone in the treatment of patients with advanced stage HCC who previously lacked any effective treatment. This clinical success has served as a major impetus to further development of molecular-targeted therapies for this cancer.

A number of trials are currently under way to determine the safety and efficacy of sorafenib in combination with other molecular-targeted agents (Table 3). Examples of these studies include a Phase III study comparing sorafenib plus erlotinib (epidermal growth factor receptor [EGFR] inhibitor) to sorafenib plus placebo (SEARCH [Sorafenib and Erlotinib, A Randomized Trial Protocol for the Treatment of Patients with HCC]) and randomized Phase II comparing everolimus (mammalian target of rapamycin inhibitor) plus

sorafenib to sorafenib alone. A number of other agents are also being explored in single arm and randomized Phase II studies. Recently, the Phase III study directly comparing sorafenib to sunitinib was terminated early due to a higher incidence of serious adverse events. While sorafenib does improve overall survival in patients with advanced HCC, progressive disease eventually develops in most patients. Failure of sorafenib may reflect the participation of alternative molecular pathways driving tumor progression. In addition to combining agents with sorafenib, ongoing trials are also targeting different molecular pathways not inhibited by sorafenib. An example is brivanib, an oral, selective dual inhibitor of the fibroblast growth factor and VEGF pathway. Brivanib has shown clinical activity and manageable tolerability as a first-line or second-line treatment in a Phase II study for patients with advanced HCC.¹⁴⁶ The positive results have led to the initiation of Phase III studies with brivanib as a first-line and second-line treatment for advanced HCC as well as in combination with TACE for intermediate stage HCC.^{147–149}

Prior to the benefits of sorafenib demonstrated by the Phase III SHARP trial, a randomized Phase II trial of patients with advanced HCC to treatment with sorafenib plus doxorubicin versus doxorubicin alone was performed.¹⁵⁰ This study was halted once the survival benefit of sorafenib was established, making sorafenib the standard of care for advanced HCC. In this study, sorafenib plus doxorubicin compared doxorubicin monotherapy improved median time to progression, overall survival, and progression-free survival. Presently, a Phase III trial by the United States cooperative group Cancer and Leukemia Group B (80802) is currently enrolling with a study design comparing single agent sorafenib versus sorafenib plus doxorubicin to further clarify if there is synergy with this combination with improved outcomes.

In addition to improving outcomes with newer treatments, there remains some uncertainty about the use of sorafenib in patients with more liver function impairment, such as those with Child–Pugh class B cirrhosis. This concern is important since the majority of patients with HCC in clinical practice may have more compromised liver function and differ from the patients in the pivotal trials that had Child–Pugh class A cirrhosis. Currently, there is limited data on the use of sorafenib in Child–Pugh class B cirrhosis and its use needs to be individualized with close monitoring and an assessment of its risk-benefit profile. Data from the GIDEON (Global Investigation of Therapeutic Decisions on HCC and of its Treatment with Sorafenib) study, which is a large global prospective, noninterventional study of

Table 3 Ongoing and planned trials in hepatocellular carcinoma

Targeted population	Goal	Design	Phase
Adjuvant	Prevent recurrences	1. Sorafenib vs placebo 2. PI-88 vs placebo	III III
Early HCC	Improve RFA	1. RFA + ThermoDox®	III
Intermediate HCC	Improve TACE	1. TACE ± sorafenib 2. TACE ± brivanib 3. TACE ± yttrium-90	II III II
Advanced HCC	First line:	1. Sorafenib ± erlotinib 2. Sorafenib vs brivanib 3. Sorafenib vs sunitinib 4. Sorafenib vs sunitinib 5. Sorafenib vs ABT-869 6. Sorafenib vs bevacizumab and erlotinib 7. Sorafenib ± doxorubicin	III III III (terminated) III III III III

Abbreviations: HCC, hepatocellular carcinoma; RFA, radiofrequency ablation; TACE, transarterial chemoembolization.

patients with unresectable HCC assigned to sorafenib, may provide more information on the safety and efficacy of sorafenib in Child–Pugh class B cirrhosis. An interim analysis reported that compared with Child–Pugh class A patients, Child–Pugh class B patients did not have a higher incidence of drug-related adverse effects, but had a higher incidence of liver-associated adverse effects. Another concern in real-life clinical practice with sorafenib is that full dosing can be challenging and a large percentage of patients require dose reductions. The concern for adverse events in this vulnerable patient population results in the consideration and initiation of lower starting doses by a large number of prescribers as presented by the GIDEON interim analysis. Presently, the authors' center is evaluating an open-label randomized study (RAMP-UP [Sorafenib Dose Ramp-Up in HCC]) to see if increasing the dose of sorafenib slowly over several weeks versus starting with the standard full dose can improve tolerance and drug delivery.¹⁵¹

Additional molecular targets for advanced HCC

Erlotinib (Tarceva®) is an EGFR tyrosine kinase inhibitor that in a single-arm Phase II trial using erlotinib monotherapy in 38 patients with advanced HCC, a benefit was observed with a median overall survival of 13 months.¹⁵² When using erlotinib and bevacizumab (Avastin®) – VEGF antagonists – together in a single-arm Phase II trial in 40 patients with advanced HCC, an impressive median survival of 15.6 months was observed.¹⁵³ This clinically meaningful result has led to a Phase II randomized study of bevacizumab and erlotinib compared to sorafenib monotherapy as a first-line treatment¹⁵⁴ and as a second-line treatment¹⁵⁵ for advanced HCC. Lapatinib (Tykerb®) is another inhibitor of EGFR that also blocks the human epidermal growth factor receptor 2 pathways. Phase II trials with lapatinib for advanced HCC have shown that this agent was well tolerated, but therapy did not meet the predefined efficacy rate.^{156,157} Similar to lapatinib, other agents targeting the EGFR pathway as monotherapy, such as gefinitib (Iressa®) and cetuximab (Erbix®), failed to show significant evidence of clinical activity.^{158,159} Cetuximab, the chimeric monoclonal antibody against EGFR, in combination with gemcitabine and oxaliplatin in a single-arm study with 45 advanced HCC patients was associated with hematologic toxicity that consisted of thrombocytopenia (24%), neutropenia (20%), and anemia (4%), and a median overall survival of 9.5 months.¹⁶⁰

Other drugs targeting various molecular pathways under active investigation for treatment of advanced HCC include: linifanib (ABT-869) in a Phase III study being

compared with sorafenib;¹⁶¹ mitogen-activated protein kinase kinase inhibitors (BAY86-9766) in a Phase II study in combination with sorafenib;¹⁶² mapatumumab (HGS-1012), a human agonist monoclonal antibody to the tumor necrosis factor-related apoptosis-inducing ligand receptor 1 in Phase I–II evaluation in combination with sorafenib;¹⁶³ everolimus (Afinitor®), an oral mammalian target of rapamycin inhibitor in Phase I–II evaluation for the treatment of advanced HCC;^{164,165} and ramucirumab (IMC-1121B), a human monoclonal antibody that binds to VEGF receptor 2 in a Phase III study as a second-line treatment in patients with advanced HCC who fail first-line treatment with sorafenib (REACH [A Study of Ramucirumab Drug Product and Best Supportive Care Versus Placebo and Best Supportive Care as Second-Line Treatment in Patients With HCC After First-Line Therapy With Sorafenib] study). Ramucirumab was also evaluated in a one-arm Phase II study of 43 patients with advanced HCC. As a single agent in sorafenib-naïve patients, it conferred moderate disease control (50%) and was associated with gastrointestinal bleeding (9%; grade 3/4), hypertension (14%; grade 3/4), and infusion-related reactions (5%; grade 3); clinical efficacy was not reported in the abstract.¹⁶⁶

Brivanib (BMS-582664), a selective dual inhibitor of VEGF receptor and fibroblast growth factor receptor signaling pathways, has been evaluated in a Phase II study as a single agent both as first-line^{146,167} and second-line¹⁶⁷ treatment. Raoul et al enrolled a total of 96 patients with advanced HCC, with 55 being treatment-naïve (Cohort A) and 41 having received previous treatment (Cohort B). In Cohort A, brivanib resulted in a disease control rate of 60% and was generally well tolerated. The patients had no skin toxicities and the most common adverse events included fatigue (45%), hypertension (45%), and diarrhea (42%).¹⁶⁷ The median overall survival for the first-line treatment cohort was 10 months. The second cohort of 41 patients (Cohort B) received brivanib as a second-line treatment after failing one prior antiangiogenic therapy – 94% had progression with sorafenib and 6% failed thalidomide. This cohort had a lower disease control rate of 46% but a similar median overall survival of 9.8 months. Brivanib is nearing completion of Phase III trial testing as a first-line treatment versus sorafenib in advanced stage HCC, 147 as a second-line treatment versus placebo in sorafenib failures,¹⁴⁸ and brivanib versus placebo in combination with TACE.¹⁴⁹ Unfortunately, the great medical need for a second-line treatment for those that fail sorafenib with advanced stage HCC will continue since a recent press release by Bristol-Myers Squibb (New York, NY)

reported that the study did not meet the primary endpoint of improving overall survival versus placebo.¹⁶⁸

Conclusion

HCC is a major global public health problem due to the rising incidence and high mortality in both developing and developed countries. In order to mitigate this important worldwide health care challenge, it is critical to detect the cancer early. Early detection allows the application of curative treatments. The epidemiology and risk factors for HCC are well known and vary with geographic region. The prevention strategy of hepatitis B vaccination is resulting in a decline in hepatitis B, but the incidence of chronic hepatitis C-related HCC is continuing to grow in the developed world. New antiviral therapies and surveillance are available that can lead to improved outcomes by decreasing the likelihood of future HCC and/or diagnosing HCC earlier. Early diagnosis of HCC is critical since the clinical outcome depends to a large extent on the ability to identify this cancer early. Resection and transplantation remain the cornerstones of curative therapy for HCC but several advances in the treatment of unresectable HCC are beginning to expand the therapeutic armamentarium. The clinical success of sorafenib in advanced HCC has led to an explosion in clinical research using additional targeted therapies alone, in combination with sorafenib, or in combination with liver-targeted therapies looking for synergy and to further improve outcomes. Results from some of these studies are anticipated soon and can potentially change current practice. As new data emerges it will be important that management of this disease continues to be performed by multidisciplinary teams.
