Increased tissue factor, MMP-8, and D-dimer expression in diabetic patients with unstable advanced carotid atherosclerosis

Abstract: Advanced atherogenesis is characterized by the presence of markers of enhanced prothrombotic capacity, attenuated fibrinolysis, and by clinical conditions associated with defective coagulation. Diabetes may be associated with enhanced lesion instability and atherosclerotic plaque rupture. Plaques obtained from 206 patients undergoing carotid endarterectomy were divided into diabetic (type 2) and nondiabetic and analyzed by Western blotting and immunohistochemistry to detect tissue factor (TF), metalloproteinases (MMP)-2, -8, -9, and fibrin/fibrinogen related antigens, and in situ zymography to detect MMP activity. Plasma samples were quantified for TF procoagulant activity, C-reactive protein, fibrinogen and D-dimer. Diabetic and symptomatic patients with hypoechogenic plaques had increased plasma TF activity and D-dimer, compared with those with hyperechogenic plaques (p = 0.03, p = 0.007, respectively). Diabetic, symptomatic patients had higher plasma D-dimer levels than asymptomatic patients (p = 0.03). There was a significant correlation between intramural TF levels and D-dimer in diabetic patients with symptomatic disease (p = 0.001, r² = 0.4). In diabetic patients, plasma fibrinogen levels were higher in patients with hypoechogenic plaques (p = 0.007). Diabetic patients with ulcerated plaques had higher plasma D-dimer and MMP-8 levels than those with fibrous plaques (p = 0.02, p = 0.01, respectively). This data suggests that currently available circulating markers may be clinically useful to select diabetic patients at higher risk of atherothrombosis. Increased procoagulant activity in diabetic patients may be linked to increased mural remodeling.

Keywords: Diabetes, atherosclerosis, carotid artery, tissue factor, D-dimer, matrix metalloproteinase.

Introduction
Diabetes mellitus is associated with severe atherosclerosis in humans (Paoletti et al 2006). Patients with metabolic syndrome are at increased risk for both progressive carotid atherosclerosis and coronary heart disease (Diamant et al 2002). Chronic perturbation of diabetic vasculature leads to increased complexity of atherosclerotic plaques (King et al 1998). Furthermore, diabetics have enhanced lesion instability (Death et al 2003).

Several studies have suggested an association between circulating tissue factor (TF) and progression of atherothrombosis. Diabetes, hypercholesterolemia, and smoking, are associated with a higher incidence of thrombotic complications. Poorly controlled diabetic patients have increased circulating TF activity associated with increased blood thrombogenicity (Viles-Gonzalez et al 2006). These findings suggest that high levels of circulating TF may be the mechanism of action responsible for increased thrombotic complications associated with the presence of diabetes (Sambola et al 2003; Steffel et al 2006; Meerarani et al 2007). Increased expression of TF in high-grade stenosis of the ICA is associated with plaque destabilization evidenced clinically both by a history of previous ischemic symptoms and the detection of microemboli in long-term transcranial Doppler ultrasound monitoring of
the ipsilateral middle cerebral artery (Jander et al 2001). Diabetics with vascular disease have raised plasma fibrinogen (Lipinski 2001; Corrado et al 2006), which is considered to be an important risk factor in atherosclerosis (Tkac et al 2003; Krupinski et al 2007). Fibrinogen remains an independent risk factor for both cardiac and extracardiac atherothrombotic complications. Fibrinogen and its effector, thrombin, substantially determine the extent and outcome of atherothrombotic complications, because they are the molecules linking the mutually dependent events in atherogenesis, coagulation/fibrinolysis, rheology, and inflammation (Shah 2006; Krupinski et al 2007a, 2007b).

The mechanisms that mediate vascular complications in diabetic patients are not yet fully understood. Patients with an increased risk of symptomatic vascular disease and development of type 2 diabetes have an atherogenic ‘prediabetic’ state. This can be measured by increased triglyceride levels, increased systolic blood pressure, and decreased levels of HDL cholesterol occurring before the onset of type 2 diabetes (Haffner 2002). Elevated glucose induces discordant metalloprotease (MMP) expression from endothelial cells and macrophages (Ho et al 2007). High glucose induces endothelial cell expression and activity of MMP-1, -2, but reduces expression of MMP-3. In monocytes MMP-9 activity and expression is induced by high glucose (Death et al 2003). Dermal fibroblasts from diabetic patients were also found to have elevated MMP-2,-3 production (Wall et al 2003). The increased MMP-1, -2, -9 activities induced by high glucose exposure could promote matrix degradation thereby accelerating atherogenesis and potentially reducing plaque stability in diabetes (Derosa et al 2007; Turu et al 2007).

This study was designed to identify links between the prothrombotic state, intramural remodeling, and inflammatory markers in diabetic patients with vulnerable carotid disease (Rubio et al 2005).

**Materials and methods**

**Patients**

Patients (n = 206) undergoing symptomatic and asymptomatic carotid endarterectomy were used in this study. Symptomatic patients presented with stroke or transient ischemic attack (TIA) in the territory of the affected carotid artery within 6 months prior to endarterectomy according to North American Symptomatic Carotid Endarterectomy Trial criteria (NASCET 1991). Patients were divided into diabetics (n = 53) and nondiabetics (n = 73) according to clinical evidence of type II diabetes (Table 1). All patients had CT-scan and MR imaging, followed by MR angiography or conventional arteriography and the degree of carotid stenosis was calculated according to Bladin and colleagues (1995). Patients were screened for the presence of bilateral pathology (>50% contralateral stenosis). Duplex colour ultrasound analysis was used to classify plaque stability in terms of hypoechogenic or hyperechogenic according to the Gray-Weale criteria (1988). The presence of vascular risk factors (VRF) was recorded and previous statin or antiplatelet treatment was noted. If a patient was anticoagulated he/she was excluded from further analysis. For quantitative assay of D-dimer expression and high sensitivity C-reactive protein (hsCRP) patients with history of acute arterial or venous thromboembolism, active infections or inflammatory conditions, renal failure, hepatic disease, neoplasms, recent trauma, or surgery were excluded. The study was approved by the local ethical committee.

**Blood sampling and tests**

Plasma samples were collected after overnight fasting and prior to surgery, frozen in liquid nitrogen and stored at −80 °C for further processing. D-dimer was measured in plasma by automated latex enhanced immunoassay on IL Coagulation Systems (IL Test D-Dimer, 20008500, Biokit, SA). HsCRP was tested in EDTA-plasma samples by particle enhanced immunonephelometry using BN Systems (Dade Behring, Marburg, Germany).

MMP-2, MMP-8, and MMP-9 levels were determined by commercially available enzyme-linked immunosorbent assay (ELISA, Biotrak Amersham Pharmacia, UK). Our laboratory reference ranges for healthy controls were: 41 ± 27.8 ng/ml

for MMP-9 (n = 62, 58% males, mean age 43 years, normal range 25–97 ng/ml), 3.10 ± 1.47 ng/ml for MMP-8 (n = 57, normal range 0.16–6 ng/ml) and 630.8 ± 101.8 ng/ml for MMP-2 (n = 40, 47% males, mean age 43 years, normal range 427–835 ng/ml). The mean intra-assay coefficients of variation were <10% for all MMPs.

Circulating TF activity was measured by Actichrome TF, a chromogenic assay (American Diagnostica, Inc., Stamford, CT, USA). This method measures the peptidyl activity of human TF in lysed cells and human plasma. Samples were mixed with human factor VIIa and human factor X. The reagents were incubated at 37 °C, allowing for the formation of the TF/factor VIIa complex (TF/VIIa), and the activation of the human factor X to factor Xa. The amount of factor Xa generated was measured by its ability to cleave Septrozyme® Xa, a highly specific chromogenic substrate for factor Xa, which was added to the reaction solution. The cleaved substrate released a para-nitroaniline chromophore into the reaction solution. The absorbance was measured at 405 nm and compared with values obtained from a standard curve generated using known amounts of active human TF.

All other standard hematological and biochemistry analysis were routinely performed at the hospital laboratory.

**Carotid specimens**

Carotid specimens were excised by the vascular surgeon without damage to the plaque surface. They were immediately rinsed in 0.9% saline and cut longitudinally into two specimens. One was snap frozen in liquid nitrogen and stored at −80 °C and the other was fixed for 24 hours in buffered formalin and later cryoprotected in 30% sucrose and frozen in OCT for histology. Plaque morphology was assessed immediately after surgery and later by histology of H&E stained sections. Plaques were classified according to AHA classification as unstable (ulcerated or ulcerated with hemorrhage) or stable (fibrous or fibrous with old hemorrhage) (Stary et al 1995).

**Western blotting**

For gel electrophoresis, samples (n = 30, 15 diabetics and nondiabetics) were homogenized with 300 µl of ice-cold homogenisation buffer containing 1% sodium deoxycholate, 1% v/v Triton X-100, 100 µM EDTA, 1 µM leupeptin, 1 µM pepstatin, 1 µM aprotinin, and 200 µM PMSF. Samples were centrifuged at 5000 rpm for 2 min and stored in aliquots at −20 °C. The protein concentration of each sample was determined using the Bradford assay. SDS-PAGE (10%) was carried out as previously described (Slevin et al 2002). Membranes were incubated overnight at 4 °C with antihuman MMP-9 and MMP-8 antibodies (Chemicon MAB13415; MAB19045, respectively) (Turu et al 2006) and anti-human antibody to TF (American Diagnostica Inc, ID4501, 1:100). The remaining procedure was performed according to standard protocols.

**Statistical analysis**

Normality of continuous variables was checked by Kolmogorov-Smirnov normality test. Normally distributed clinical, histological and Western blotting variables were compared between groups by analysis of variance (ANOVA). When samples were not normally distributed, Kruskal-Wallis was used. Differences in frequencies of categorical variables were checked by chi-square test.

**Results**

Table 1 summarizes clinical characteristics of the studied population. There was no difference in age, sex, vascular risks factor distribution, presence of bilateral carotid disease, carotid stenosis severity, plaque stability on ultrasound, coexisting coronary artery disease (CAD), or peripheral vascular disease (PVD) between diabetic and nondiabetic patients. Furthermore, as summarized in Table 2, there were no differences in biochemical parameters studied between diabetics and nondiabetics. However, when diabetes was associated with symptomatic carotid disease or vulnerable carotid plaques, differences were significant as presented below.

activity compared with nondiabetics (16.34 PM vs 10.4 PM, p = 0.03; Figure 1a). Regression analysis in the same group of patients showed a strong correlation between TF activity in plasma and intramural levels of MMP-8 (p = 0.03, r² = 0.2, Figure 1b). There was also a correlation between intramural TF levels and both circulating active MMP-8 and intramural D-dimer in symptomatic, diabetic patients with hypoechoogenic plaque on ultrasound (p = 0.02, r² = 0.6, Figure 2a; p = 0.001, r² = 0.4, Figure 2b, respectively).

Markers of fibrinolysis and inflammation
Diabetics with symptomatic carotid disease had higher levels of plasma D-dimer if the plaque was hypoechoic on ultrasound as compared with patients with hyperechoic plaques (p = 0.007, Figure 3a). Diabetics with histologically identified ulcerated plaques had higher plasma D-dimer than diabetics with fibrous plaques (p = 0.02; Figure 3b). Diabetic patients with symptomatic carotid disease had higher plasma D-dimer than nondiabetics (p = 0.03; Figure 3c). Plasma fibrinogen, but not CRP levels were higher in diabetics with hypoechoic plaques, identified by ultrasound, as compared with diabetics with hyperechoic plaques (4.6 mg/l vs 3.6 mg/l, p = 0.007).

Markers of plaque remodeling
Diabetic patients with histologically identified ulcerated carotid plaques had significantly higher plasma levels
Markers of high risk of thrombosis in diabetic atherosclerosis

of MMP-8 than diabetics with stable, fibrous plaques ($p = 0.01$, Figure 4a). In symptomatic, diabetic patients with hypoechoic plaques, identified by ultrasound, there was a correlation between total cholesterol levels and intramural MMP-8 levels ($p = 0.02$, $r^2 = 0.5$, Figure 4b).

On western blot diabetic patients had higher plaque TF, active MMP-8, but not MMP-9 expression. The later was more expressed in diabetics with ulcerated, hemorrhagic plaques. Representative western blots are presented in Figure 5.

**Figure 3** (A) Diabetics with symptomatic carotid disease had higher levels of plasma D-dimer if the plaque was hypoechoic on ultrasound as compared with patients with hyperchoic plaque ($p = 0.007$). (B) Diabetics with ulcerated plaque had more plasma D-dimer than diabetics with fibrous plaque ($p = 0.02$). (C) Diabetics with symptomatic carotid disease had higher levels of plasma D-dimer as compared with diabetic asymptomatic patients ($p = 0.03$).

**Figure 4** (A) Diabetic patients with ulcerated carotid plaque on morphology had higher plasma levels MMP-8 than diabetics with stable, fibrous plaque ($p = 0.01$). (B) In symptomatic, diabetic patients with hypoechoic plaque on ultrasound on regression plot there was correlation between total cholesterol levels and intramural MMP-8 levels ($p = 0.02$, $r^2 = 0.5$).

**Abbreviations:** MMP, metalloproteinases.
In this study, diabetic patients with unstable carotid disease measured by the presence of symptomatic carotid disease, plaque echogenicity on ultrasound, or plaque vulnerability as evidenced by ulceration on histology, had significantly higher levels of markers of hemostasis, fibrinolysis and plaque remodeling compared with diabetics with stable disease.

TF is thought to be responsible for the prothrombotic state in patients with diabetes, and development of significant carotid artery stenosis with associated plaque remodeling (Sambola et al 2003; Vaidyula et al 2006). Mononuclear cells and monocytes from patients with type 2 diabetes have increased procoagulant activity as measured by TF expression (Konieczkowski and Skrinska 2001). Increased synthesis of TXA2 and TF may potentiate thrombosis and increase fibrin deposition, events that play primary roles in the development of vascular disease. During hyperglycemia-hyperinsulinemia, which is a characteristic of type 2 diabetes, elevation of plasma coagulation factors may constitute a potential for enhanced thrombin generation and thrombosis when triggered by exposure of TF, such as during arterial plaque rupture (Corti et al 2004; Vaidyula et al 2006). Changes of the TF pathway of blood coagulation have been described in diabetes and could be involved in its vascular complications.

Samad and colleagues (2001) found that hyperinsulinemia associated with insulin-resistant states, such as obesity and noninsulin-dependent diabetes mellitus, induced local TF gene expression in multiple tissues, thus contributing via the TF pathway to the increased risk of atherothrombotic disease. There was a strong correlation between expression of the receptor for advanced glycation end products (RAGE) and TF, in long-standing uncontrolled type 2 diabetics (Buchs et al 2004). In our study, diabetics with symptomatic carotid disease had increased circulating tissue factor. Numerous hemostatic factors like vWF, t-PA, PAI-1 are increased in patients with type 2 diabetes or impaired glucose tolerance. Recently, TF was shown to be associated with existing microvascular and neurogenical complications in patients with type 2 diabetes, and also correlated with tPA and vWF expression. Patients with diabetes and TF concentrations of >3,000 pg/ml were 15 times more likely to present with microvascular disease and 10 times more likely to have neurogenical complications (Sommeijer et al 2006). In elderly patients with IGT, intermediates of the TF pathway, ie, TFPI are already increased as compared with normal subjects. Interestingly, endothelium-dependent hemostatic markers do not appear to correlate with lipid metabolism (Leurs et al 2002)

Cell-derived microparticles support coagulation and inflammation and they may be involved in accelerated atherosclerosis in diabetic patients (Morel et al 2006). TF, possibly of granulocytic origin, was exposed on microparticle subpopulations in asymptomatic patients with well-regulated
type 2 diabetes. TF-positive microparticles were associated with components of the metabolic syndrome but not with coagulation. Thus, the presence of TF on microparticles may be involved in processes other than coagulation, including transcellular signaling or angiogenesis (Diamant et al 2002).

In this study population no differences in markers of thrombosis or plaque stability were found between diabetics and nondiabetics. However, diabetic and symptomatic patients with hypoechoic plaques, identified on ultrasound, had increased expression of circulating and intramural markers of thrombosis, fibrinolysis, and plaque remodeling as compared with patients with stable disease. Other factors and not only diabetes itself may affect changes within the arterial wall and subsequent remodeling leading to symptomatic vascular disease. In noncomplicated patients, the increase in FVII and TFPI was highly dependent on obesity index and age rather than on diabetes itself (Vambergue et al 2001). In the study described here, diabetic patients with hypercholesterolemia had higher intramural MMP-8 levels. Tissue factor activity correlated with intramural MMP-8 levels in diabetics with vulnerable carotid disease, suggesting that plaque remodeling may induce prothrombotic activity. Furthermore, in this vulnerable group of patients there was a significant correlation between total cholesterol levels and intramural MMP-8 and the presence of intramural TF and circulating active MMP-8. Independent of plaque stability, in diabetic patients, there was correlation between intramural MMP-8 and circulating TF activity. MMP-8 levels are of special interest since it is known to be released from neutrophils at sites of inflammation and vascular disease and can cleave TF pathway inhibitor, thereby decreasing its anticoagulant activity. Thus, the presence of TF on microparticles and components of the metabolic syndrome may have further pathophysiological implications in a view of recent findings suggesting that statins may inhibit plaque RAGE expression by inhibiting the biosynthesis of PGE2-dependent MMPs (Cuccurullo et al 2006). Further studies should address to answer if by control of plaque stability we also reduce prothrombotic state in diabetic patients.

Prothrombotic markers were independent from markers of inflammation like CRP, fibrinogen or leucocyte count. Our results, demonstrate a link between the processes of plaque remodeling and increased risk of thrombosis. Our study suggests, that diabetics may be a choice group for identification of key molecules participating in atherosclerosis and related risks of vascular complications. Identification of circulating risk molecules may directly reflect local advances in atherosclerosis and may help to identify diabetic patients with high risk of vascular complications.
