Abstract: Cell adhesion molecules (CAMs) mediate interactions between cells and their surroundings that are vital to processes controlling for cell survival, activation, migration, and plasticity. However, increasing evidence suggests that CAMs also mediate mechanisms involved in several neurological diseases. This article reviews the current knowledge on the role of CAMs in amyloid- β (A β) metabolism, cell plasticity, neuroinflammation, and vascular changes, all of which are considered central to the pathogenesis and progression of Alzheimer's disease (AD). This paper also outlines the possible roles of CAMs in current and novel AD treatment strategies.

Keywords: cell adhesion molecules, Alzheimer's disease, neuroinflammation, plasticity, amyloid-beta, vascular changes

Introduction

Interactions between cells and the surrounding extracellular matrix (ECM) are crucial to processes controlling for cell proliferation, activation, migration, and survival. These interactions are dependent on specific adhesion processes that are orchestrated by a group of molecules referred to as cell adhesion molecules (CAMs). CAMs are transmembrane proteins with a cytoplasmic tail. Based on their specific molecular structures, they are generally classified into four major CAM families: selectins, integrins, immunoglobulin (Ig)-like CAMs (Ig-CAMs), and cadherins (schematically illustrated in Figure 1). These CAM families can be further divided into subfamilies (see Table 1).

The selectin family consists of three known members that mediate the initial steps of the leukocyte adhesion cascade,¹ the lymphocyte homing receptor (L-selectin), the endothelial leukocyte adhesion molecule (E-selectin), and the platelet-activation-dependent granule-external protein (P-selectin). All selectins interact with sialylated glycans in a Ca²⁺-dependent manner. As implicated by their names, L-selectin is primarily expressed by leukocytes, E-selectin by activated endothelial cells, and P-selectin by platelets and endothelial cells.² Soluble forms of all three selectins can be found in both plasma and in cerebrospinal fluid (CSF)^{3–6} and appear to reflect the activation state of the originating cells.

Integrins belong to a family that includes 18 alpha and 9 beta subunits.⁷ The subunits form at least 24 different heterodimeric receptors, and through these receptors, cells communicate with the ECM and surrounding cells, both outside-in and inside-out.⁸ When the ECM or CAMs expressed on neighboring cells adhere to

Figure 1 Schematic illustration of the various CAM structures. Ig-like CAMs are defined by one or more extracellular Ig repeats of 60 to 100 amino acids that form the active adhesion site and a transmembrane segment with a cytoplasmic tail. Classical cadherins have five extracellular cadherin repeats, a single transmembrane domain, and an intracellular tail. Integrin heterodimeric receptors are formed by α and β transmembrane units. Selectins have a short cytoplasmic carboxyl terminus, a transmembrane sequence followed by complement regulatory-like molecules, and an extracellular component containing an epidermal growth factor-like domain and an amino terminal domain that is homologous to C-type lectins. integrins, recruitment of cytosolic non-receptor tyrosine kinases (NRTK) and cytoskeleton proteins (CSK) occur and form focal adhesion complexes (FAC). These complexes associate with the actin cytoskeleton and multiple signaling pathways that involve processes such as cell survival, inflammation, and angiogenesis, while synaptic transmission becomes efficiently regulated.⁹ Integrins are found on most cells throughout the brain and are region-specific as well as cell-type-specific.⁹ In addition, some integrins are known to actively shed from the cell surface in response to environmental changes such as inflammation.¹⁰

The Ig-CAMs are defined by one or more Ig repeats of 60 to 100 amino acids forming the active adhesion site. CAMs in this family can be found both in the periphery, where Ig-CAM mediated interactions are mostly heterophilic, and in the nervous system, where interactions are predominantly homophilic.¹¹ Several Ig-CAM members appear to be specific to nervous tissue^{12,13} where they play vital roles in, for example, neurogenesis, neurite elongation, and brain plasticity. Furthermore, Ig-CAMs can be shed from cell membranes¹⁴ and the soluble versions may have separate effects from the cell-bound forms.¹⁵

Cadherins, particularly the classical cadherin and protocadherin subfamilies, are found throughout the nervous system. The two cadherin subfamilies are found mostly on neuronal synapses^{16,17} and extensive studies have shown that classical cadherins play a crucial role in neuronal plasticity and synaptogenesis.¹⁷ The functions of classical cadherins are mediated by a complex that

is formed between the cytoplasmic tail of the cadherin and the cytosolic catenins, which are linked to the actin cytoskeleton.¹⁷ Like the other CAMs, cadherins are sensitive to proteolytic shedding.¹⁸

Collectively, CAMs orchestrate important functions in many vital physiological processes. However, increasing evidence suggests that CAMs are involved in the pathophysiology of several neurological diseases. This review summarizes current knowledge on the role of CAMs in events considered central to the pathogenesis and progression of Alzheimer's disease (AD) such as amyloid- β (A β) metabolism, neuronal plasticity, inflammation, and vascular changes (data summarized in Table 2). We also discuss the potential impact of the involvement of CAMs in these processes in terms of cognitive symptoms in AD patients. Finally, this paper reviews current AD treatment strategies and the possible use of CAMs as targets in current and future AD treatments.

Alzheimer's disease pathogenesis

Neuropathologically, AD is primarily characterized by intra-neuronal neurofibrillary tangles (NFTs) of hyperphosphorylated tau and extracellular deposits of mainly aggregated A β peptide, known as senile or neuritic plaques.¹⁹ According to the amyloid cascade hypothesis, the aggregation and deposition of A β in brain tissue is key to AD pathogenesis with the formation of tau pathology, inflammatory processes, and neurodegeneration as downstream events.²⁰ The A β peptide is generated by proteolytic processing of the amyloid precursor protein (APP) via sequential cleavage by the

enzymes β -secretase 1 (BACE 1) and γ -secretase of which the latter is a complex consisting of presenilin 1 (PSEN1), presenilin 2 (PSEN2), and nicastrin.²¹ Genetic evidence links mutations of the genes encoding PSEN1 and PSEN2 to the familial early onset form of AD (EOAD).²² Furthermore, the presence of the $\epsilon 4$ allele of apolipoprotein E (APOE) – the most well described genetic risk factor for sporadic AD, known as late onset AD (LOAD)²³ – was shown to promote A β fibrillogenesis, deposition, and plaque formation.²⁴ Therefore, imbalanced A β metabolism with increased A β production and insufficiently augmented A β clearance in EOAD, as well as normal A β production, but defective A β clearance in LOAD, are believed to be central events in the development of AD.

Next to the core pathological events of A β deposition and intraneuronal tau accumulation, the presence of inflammatory processes, mainly driven by glial cells, are

well described findings in the brains of patients with AD.²⁵ Numerous studies have demonstrated increased levels of inflammatory markers in the brain tissue as well as in the CSF and plasma of AD patients,^{26,27} and epidemiological studies have suggested that non-steroidal anti-inflammatory treatment may reduce the risk and slow down the progression of AD.²⁵ Also, neurovascular alterations and white matter lesions reflecting cerebrovascular pathology as well as blood brain barrier (BBB) alterations have frequently been described in dementia disorders such as AD.²⁸ Vascular pathology has even been proposed as a causal or contributing factor in at least 50% of all dementia cases.²⁹ Importantly, most AD patients are affected by the vascular deposition of A β , cerebral amyloid angiopathy (CAA).³⁰

The alteration of the glutamatergic and cholinergic systems are other well-described AD features. The glutamatergic aberration, including glutamate excitotoxicity mediated through glutamate receptors such as N-methyl-D-aspartate receptors (NMDARs), can either be caused by an A β -induced increase in glutamate release or a decrease in glutamate uptake. Furthermore, the loss of cholinergic neurons and various subtypes of acetylcholine receptors are hallmarks of AD, and may interfere with the cholinergic mechanisms that contribute to glutamatergic transmission and synapse plasticity. Together, these alterations may contribute to a decline in cognitive functions.^{31–33}

Not all of the described pathological events can be directly linked to the cognitive deterioration associated with AD, which causes uncertainty surrounding the potential causal roles of these events. Approximately one-third of cognitively normal elderly subjects display some degree of AD pathology and many of these individuals would fulfill the criteria for postmortem AD diagnoses despite the absence of cognitive symptoms. Attempts to elucidate the correlation between postmortem findings and clinical symptoms displayed a better correlation between neurofibrillary tau pathology, rather than amyloid pathology, and cognitive impairment.^{34,35} However, the best morphological correlate of cognitive dysfunction in clinical AD appears to be loss of synapses^{36,37} with synaptic injury developing early in AD pathogenesis.^{38,39}

Taken together, the current understanding supports the notion that AD results from a series of slowly developing neuropathological changes with a long asymptomatic phase preceding cognitive impairment. Therefore, early treatment strategies may prove to be the most efficient mode of prevention.

Table 2 CAMs linked to AD pathological events

Cell adhesion molecule	Mechanism	Reference
Neuronal plasticity		
NCAM	Increased expression in hippocampus of AD brain, decreased expression in frontal/temporal cortex of AD brain, tendency to increased CSF levels in AD patients	43–46
LICAM	Increased in CSF from AD patients	49
N-cadherin	Cleavage inhibited and upregulated/downregulated in response to A β in vivo, synapse stabilization dependent on presenilin cleavage	18,52–54,56,57,59,60
Integrin unit α v	Mediate A β -induced LTP inhibition	61
Aβ metabolism		
Integrin unit α 4	Increased in aged brain, found adjacent to plaques	62
Integrin unit β 3	Found adjacent to plaque and tangles	63
α 5 β 1	Involved in degradation of A β in vitro	67
Integrin/FAK	Involved in modulation of A β neurotoxicity	65
α 1 β 1	Downregulated by A β in vitro, rescued by estradiol	66
N-cadherin	Increased APP dimerization, A β release, decrease A β 42/40 ratio	70,71
E-cadherin	Promote APP derivate, inhibit A β production	75
Integrin unit β 1	Mediate microglial internalization of fibrillar A β	68
Immunological events		
ICAM-1	Upregulated in response to A β in vitro, increased plasma levels in AD patients, increased expression in A β plaque, identified in plaque, correlated with hyaluronic acid in female AD	84,90,92–96
VCAM-1	Upregulated in response to A β in vitro, increased plasma levels in AD patients, decreased CSF levels in AD patients,	84,92,93
PECAM-1	Involved in A β -induced transendothelial migration of monocytes, increased plasma levels in AD patients	84,92
α 6 β 1	Mediate fibrillar A β induced microglial activation	100
α v β 3/5	Mediate neuronal phagocytic signal to microglial	101
α L β 2	Increased expression in AD brain	143
α M β 2	Increased expression in AD brain, mediate A β induced neuroinflammation	103,143
α X β 2	Increased expression in AD brain	143
Vascular changes		
E-selectin	Increased in plasma of AD patients with vascular changes	93,108
P-selectin	Increased in plasma of AD patients with fast cognitive decline	
α v β 3	Increased in angiogenic vessels in AD brain	114

Abbreviations: A β , amyloid- β ; AD, Alzheimer's disease; APP, amyloid precursor protein; CAM, cell adhesion molecule; CSF, cerebrospinal fluid; E-cadherin, epithelial cadherin; E-selectin, endothelial leukocyte cell adhesion molecule; FAK, focal adhesion kinase; ICAM-1, intercellular cell adhesion molecule 1; LICAM, LI cell adhesion molecule; LTP, long-term potentiation; N-cadherin, neuronal cadherin; NCAM, neural cell adhesion molecule; PECAM-1, platelet endothelial cell adhesion molecule 1; P-selectin, platelet-activation-dependent granule-external protein; VCAM-1, vascular cell adhesion molecule 1.

CAMs in altered synaptic and neuronal plasticity

The neurodegeneration and subsequent massive neuron loss associated with AD is considered to be paralleled by altered neurogenesis, which may be induced by A β -related mechanisms.⁴⁰ In the adult brain, neurogenesis has been identified in the hippocampus and the subventricular zone (SVZ).^{41,42} Expression of the neural cell adhesion molecule (NCAM), especially the highly polysialylated NCAM (PSA-NCAM) is considered an indicator of neurogenesis, neuronal remodeling, and plasticity, and has therefore been evaluated in AD brains. Results obtained by the use of immunohistochemistry and enzyme-linked immunosorbent assay (ELISA) suggest that alteration in NCAM expression in AD

patients is brain-area dependent. Expression of hippocampal PSA-NCAM in AD patients was shown to increase with disease severity,^{43,44} whereas fewer NCAM positive neurons as well as lower NCAM expression were found in the frontal and temporal cortex of AD patients versus normal aging controls.^{45,46} The physiological roles of the soluble forms of NCAM are not completely elucidated but may implicate long-term potentiation (LTP), which is a cellular model of learning and memory.⁴⁷ In a small study on Parkinson's disease and AD patients, the latter displayed increased CSF levels of the soluble NCAM-120 splice variant compared to the controls.⁴⁸ Similarly, another study demonstrated a tendency towards elevated levels of soluble NCAM in the CSF of AD patients versus the controls.⁴⁹ The latter study also showed that CSF

concentrations of the L1 cell adhesion molecule (L1CAM), postulated to be involved in neurite elongation, fasciculation, and migration⁵⁰ increased by 48% in AD patients versus the controls.⁴⁹ The significance of these findings and the impact of altered NCAM and L1 expression on cognitive performance require further investigation.

As mentioned previously, synapse loss is strongly correlated with cognitive decline in AD patients.³⁷ Since cadherins, particularly neuronal cadherins (N-cadherins), are important for synaptic formation and stability,⁵¹ they have become interesting research targets for their possible role in AD pathology and clinical disease manifestations. Studies of mice cortically injected with A β showed that the peptide inhibited cleavage,⁵² but increased the expression, of N-cadherin.⁵³ In contrast, a study on murine primary neurons showed that A β 42 exposure decreased N-cadherin expression through the glutamate N-Methyl-D-aspartate (NMDA) receptors and that the N-cadherin downregulation was followed by phosphorylation of the p38 mitogen activation protein kinase (p38 MAPK) and tau. Therefore, the decreased N-cadherin expression may be linked to tau pathology and, ultimately, to cognitive malperformance.⁵⁴ The activation of p38 MAPK is noteworthy since it is an intracellular transduction factor that becomes activated by oxidative stress and cytokine secretion,⁵⁵ both of which are processes linked to AD pathology.

As previously mentioned, mutations in the genes encoding for the presenilins, foremost known as the catalytic component of the A β generating γ -secretase, are linked to EOAD.²¹ However, presenilin is also recruited to the synaptic adhesion site, where it binds to the cadherin-catenin complex and, in response to membrane depolarization or NMDAR stimulation, cleaves N-cadherin.¹⁸ Support for its proteolytic effect on N-cadherin is found in functional studies showing a complete loss of N-cadherin cleavage caused by mutations in the PSEN1 gene.⁵⁶ The cleavage of N-cadherin was also proven to generate a cytosolic protein fragment, termed the carboxy-terminal fragment of N-cadherin (N-Cad/CTF2). This fragment was also shown to disturb the interaction between cyclic adenosine monophosphate (cAMP), response element-binding (CREB), and CREB binding protein (CBP),⁵⁷ a complex that is critical to several processes affected by AD, such as synaptic plasticity and memory.⁵⁸ Interestingly, recruitment of presenilin to the cadherin-catenin complex occurs at the expense of the presenilin/ γ -secretase cleavage of APP,⁵⁹ which inhibits the amyloidogenic pathway. Finally, presenilin may also play a role in the trafficking

of N-cadherin since cells that express mutant presenilin express less N-cadherin⁶⁰ which, as previously mentioned, may lead to tau phosphorylation.⁵⁴

Numerous studies have shown that integrins are also involved in synaptic transmission, synaptic plasticity, and LTP.⁹ Therefore, it is interesting that a preclinical study demonstrated the preventative role of integrin α_v on A β -induced LTP inhibition,⁶¹ which when extrapolated, may counteract the mild cognitive impairment and synaptic loss observed in the early stages of AD.

Taken together, increasing evidence suggests that molecules belonging to several CAM families are engaged in neurogenesis, synaptic, and neuronal plasticity, all of which are affected by AD. Therefore, specific CAMs may constitute novel targets in strategies aimed at restoring these processes in AD, which may ultimately lead to preserved cognitive functions.

Evidence linking CAMs to A β metabolism

The significant association between A β - and AD-related synaptic alterations highlights the importance of elucidating the potential links between CAMs and the production, degradation, and biological functions of A β .

Immunohistological studies of brain tissue suggest that integrins may play a specific role in A β pathology. Expression of the α_4 integrin unit in hippocampal pyramidal neurons and some neocortical neurons is increased in aged individuals.⁶² Furthermore, increased expression of α_4 and β_3 , their ligands fibronectin, and vitronectin, as well as the CSK proteins, paxillin and hydrogen peroxide-inducible clone 5 (Hic-5), were found in plaques and/or tangles in AD brain tissue.⁶²⁻⁶⁴ Moreover, integrins may also mediate A β neurotoxicity. For instance, when bound to integrins, A β induced rapid phosphorylation of the NRTK focal adhesion kinase (FAK) and paxillin, which in turn activated an incomplete anti-apoptotic signaling pathway and tau phosphorylation.⁶⁵ It is worth noting that neuronal cells can be rescued from A β -induced downregulation of $\alpha_1\beta_1$ and cell cycle arrest in the presence of 17 β -estradiol, which suggested an interesting mechanism underlying the previously demonstrated increase of AD in menopausal women.⁶⁶ Interestingly, an in vitro study on human neuroblastoma cells suggested that the integrin receptor, $\alpha_5\beta_1$ (cluster of differentiation [CD] 49e), may play a role in the internalization and degradation of exogenous A β .⁶⁷ Furthermore, the β_1 integrin could mediate the microglial internalization of fibrillar,⁶⁸ but not soluble A β ,⁶⁹ suggesting that this integrin may be important

at different stages of AD, where for instance, A β becomes more fibrillar at more advanced disease stages.

Additional evidence supporting links between CAMs and AD pathology shows that adhesion based on N-cadherin increased APP dimerization and A β release, whereas the ratio of A β 42/40 was decreased.^{70,71} Another classical cadherin, epithelial cadherin (E-cadherin), also affected A β levels. This cadherin subtype is primarily expressed on epithelial cells,⁷² but is also found on hippocampal synapses.^{73,74} E-cadherin-catenin complexes recruit and can be cleaved by presenilin, similar to N-cadherin-catenin complexes. The cleavage product in this pathway, called carboxy-terminal fragment of E-cadherin (E-cad/CTF2), has been shown to promote the lysosomal degradation of APP derivatives and to inhibit A β production.⁷⁵

CAMs in AD neuroinflammatory events

Transendothelial migration of leukocytes to sites of inflammation is central to immunological processes that respond to tissue damage in the periphery. However, under certain conditions such as in multiple sclerosis (MS),⁷⁶ brain malignancies,^{77,78} and brain infections,^{79–82} leukocytes can also infiltrate the central nervous system (CNS) by crossing the BBB. The migration of leukocytes depends on integrin expression on the surface of the leukocytes and Ig-CAMs, including the intercellular cell adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), and the platelet endothelial cell adhesion molecule (PECAM-1) present on endothelial cells.¹ Expression of ICAM-1 can be upregulated in vitro on primary cultures of human brain microvessel endothelial cells by cytokines such as γ -interferon, interleukin (IL)-1, tumor necrosis factor- α (TNF- α), and endotoxin.⁸³ Experimental studies performed on human brain endothelial cells demonstrated an A β -induced time-dependent increase in ICAM-1 and VCAM-1 expression. The same study showed the augmented adhesion and transendothelial migration of monocytic cells involving PECAM-1 upon A β interaction.⁸⁴ Interestingly, soluble ICAM-1 could block lymphocyte adhesion to cerebral endothelial cells, which stands in direct opposition to the role of cell-bound ICAM-1.¹⁵ Furthermore, it has been demonstrated that ICAM-1, VCAM-1, and PECAM-1 not only engage in transendothelial migration of leukocytes but also serve as signal transducers that initiate endothelial signaling and influence the progression of neuroinflammation.⁸⁵ Increased levels of both ICAM-1 and PECAM-1 have also been proposed as indicators of inflammatory conditions in the CNS^{86,87} and could originate from

activated glial cells.⁸⁸ Similarly, Rentzos et al found increased ICAM-1 levels in AD in the absence of endothelial activation and, therefore, proposed a neural, rather than endothelial, origin of ICAM-1.^{89,90} The authors also displayed a positive correlation between increased levels of CSF ICAM-1 and disease severity, as assessed by mini-mental state examination (MMSE) scores.

The concentrations of the soluble forms of ICAM-1, VCAM-1, and PECAM-1 in patients with AD as well as other neurodegenerative diseases such as dementia with Lewy bodies (DLB) have been evaluated in several studies.^{89–92} In patients with LOAD, Zuliani et al found increased levels of plasma VCAM-1,⁹³ while this study found that AD and DLB patients exhibited higher plasma levels of soluble ICAM-1 and PECAM-1, but not VCAM-1.⁹² Discrepancies between the VCAM-1 plasma levels in these studies might be due to dementia severity – AD patients with moderate dementia may exhibit normal plasma VCAM-1 levels while patients with more severe dementia may exhibit different levels.^{92,93} Altered plasma levels of ICAM-1 were shown to be unrelated to the risk of dementia in non-demented individuals; therefore, increased levels might be secondary to the processes that lead to the onset of dementia.⁹¹ In direct opposition to the results on plasma, this review found that the CSF concentrations of VCAM-1 were significantly lower in patients with AD and DLB. In patients with AD, brain tissue ICAM-1 was repeatedly identified in plaques;^{94–96} however, this study only found increased CSF concentrations of soluble ICAM-1 in patients with DLB.⁹² Therefore, the soluble fraction of these CAMs may not necessarily reflect the amount of the cell-membrane-bound forms. In a recent study we also showed that CSF levels of ICAM-1 in female AD patients correlated with levels of hyaluronic acid, an adhesion molecule implicated in both inflammatory events and vascular changes.⁹⁷ The main significance of the described altered levels of Ig-CAMs in AD requires further investigation as neuroinflammation in AD appears to take place without any apparent influx of leukocytes from the blood.⁹⁸ Thus, the altered levels of the soluble forms of Ig-CAMs may reflect inflammatory processes unrelated to cognitive performance (as assessed with MMSE). Alternatively, they may mediate functions that are currently unknown in relation to AD pathology.

In addition to Ig-CAMs, integrins can also be linked to AD neuroinflammation. The integrins on the surface of leukocytes are considered important for the presentation of antigen in the CNS.⁹⁹ Similarly, microglia express several integrins that can be upregulated when the cells are activated in response to inflammation and injury. A recent

study showed that microglia could interact with fibrillary A β through a complex including $\alpha 6\beta 1$ and B-class scavenger receptor, CD36. This interaction induced proinflammatory activation of the microglia, which led to increased production of cytokines and chemokines.¹⁰⁰ Moreover, results obtained from mixed neuron-glia cell cultures from cerebellum showed that neurons, when exposed to A β , signal a phagocytic request to microglia that is mediated through binding between phosphatidylserine (PS) on the neuron surface and the $\alpha v\beta 3/5$ integrin receptors on microglia.¹⁰¹ Other integrins such as $\alpha L\beta 2$ (CD11a), $\alpha M\beta 2$ (CD11b), and $\alpha X\beta 2$ (CD11c) found in immunohistological studies on the temporal cortexes of AD patients, were found to be strongly upregulated on the surface of activated microglia in presence of A β .¹⁰² Antibodies blocking the microglial $\alpha M\beta 2$ (CD11b) have also been shown to attenuate inflammatory reactions, vascular responses, and neurodegeneration induced by the injection of A β into rat hippocampuses.¹⁰³

The proinflammatory activation of microglia is also associated with changes in β -catenin, a protein that links cadherins to the intracellular actin. A study performed on brain tissue from AD patients and transgenic AD mice demonstrated the increased expression of β -catenin in activated morphologically transformed microglia. The authors of this study also used *in vitro* studies to show that Wnt signaling, a pathway controlling β -catenin metabolism, regulates the gene expression of microglial proinflammatory cytokines.¹⁰⁴

Collectively, these data indicate that CAMs of the integrin and Ig-CAM families are involved in AD neuroinflammatory events, and some of these molecules may function as inflammation markers whereas others may play active roles in mediating inflammation.

Role of CAMs in vascular changes linked to AD

Several CAMs that are specifically involved in endothelial alterations, as imposed by vascular alterations and CAA in AD, have been the focus of attention in studies aimed at characterizing the vascular component frequently found in AD. Based on the clinical and epidemiological evidence supporting the links between vascular risk factors and AD, Borroni et al investigated the peripheral blood concentrations of E-selectin in age-matched controls and AD patients with mild dementia. In line with the notion of endothelial dysfunction in AD, the study demonstrated significantly increased E-selectin levels in the AD group, which indicates that endothelial dysfunction in AD could potentially be monitored in peripheral blood.¹⁰⁵ However, two recent studies could not

confirm altered E-selectin levels in AD patients. The authors of the latter studies investigated soluble CAMs in patients with various neurological disorders including AD patients without the vascular component.^{90,106} However, when the authors divided the subjects into groups with small or large vessel disease confirmed by computer tomography (CT) scans, the patients with vessel disease exhibited significantly increased E-selectin compared to the group with no vascular lesions.⁹³ Therefore, altered E-selectin levels in AD appear to be related to cerebrovascular lesions.

In the periphery, platelets contain and metabolize the A β precursor protein APP, and altered APP processing in platelets of AD patients has been suggested to reflect chronic platelet activation in these patients.¹⁰⁷ Furthermore, treatment with acetylcholinesterase inhibitors (AChEI) influences APP metabolism in platelets, which may be modulated by the APOE genotype.¹⁰⁸ Interestingly, platelet activation was recently reinvestigated and suggested as a prognostic biomarker for cognitive decline in AD patients. Patients with faster cognitive decline demonstrated significantly higher baseline expression of platelet activation markers including P-selectin.¹⁰⁹ The authors of the study proposed several mechanisms for how platelet activity could contribute to dementia progression including triggering perivascular inflammation, induction of vasoconstriction, and consecutive brain hypoperfusion in addition to contributing to the peripheral A β pool. In a recent study of platelet activation in sporadic AD patients, Järemo and colleagues found that circulating a lower density platelet population exhibits a reduced activation state, as assessed by the amount of platelet surface bound fibrinogen.¹¹⁰ Therefore, the activation of different platelet populations appears to be related to AD. The role of P-selectins in these processes is yet to be determined, but P-selectin antagonists, as modulators of inflammation, have been proposed in vascular pathologies such as atherosclerosis.¹¹¹

Next to CAMs of the selectin family, integrins are also related to vascular processes. For instance, the increased expression of $\beta 3$ integrin on endothelial cells is a well-described marker for ongoing angiogenesis.¹¹² Studies on brain tissue demonstrated upregulated $\alpha v\beta 3$ (CD51) expression in AD patients,¹¹³ a finding that supports previous results proposing increased angiogenesis in AD patients.¹¹⁴ The upregulation of this integrin was also shown to correlate with A β load in the hippocampus and neurofibrillary tangles in the midfrontal cortex.¹¹³ Further investigation is required to determine whether there is a direct or an indirect link between $\alpha v\beta 3$, AD pathology, and cognitive deterioration. In sum, the increasing evidence regarding the potential causal role

of vascular factors in AD pathogenesis warrants the further investigation of CAMs.

Currently available AD treatment options

To date, there is no approved pharmaceutical drug for the prevention or cure of AD. Instead, the available therapy consists of symptomatic treatment based on glutamatergic and cholinergic alterations, which at certain stages of AD can slow the disease's progression by boosting neuronal activity. Acetylcholinesterase inhibitors were the first AD pharmaceuticals to be approved, and today, the second generation of AChEIs (donepezil, rivastigmine, and galantamine) is the first line of pharmacotherapy for mild to moderate AD. By blocking the enzyme, acetylcholinesterase, AChEIs prevent the breakdown of acetylcholine in the synaptic cleft and partly replace the cholinergic transmission that is lost in AD patients.¹¹⁵ AChEIs have also shown favorable effects on the documented impaired vasodilation¹¹⁶ and neurovascular coupling (regulation of blood flow demand in brain areas)^{117,118} found in AD patients. Moreover, a number of studies have presented evidence of the antiinflammatory and antiamyloidogenic properties associated with AChEI.^{119,120} These findings can be related to the previously mentioned effects of AChEI on platelet APP metabolism.¹⁰⁸

Memantine, a noncompetitive antagonist of the glutamate NMDA receptor, is the second type of medication approved for AD treatment and has documented effects alone or in combination with AChEI on moderate to severe AD. Its primary effect is the inhibition of pathological activation of NMDARs, which prevent excessive glutamatergically-induced Ca^{2+} influx and cell death.¹²¹ In addition, results from preclinical studies suggest that memantine and NMDA antagonists could reduce the secretion of proinflammatory cytokines by blocking glutamate receptors on glial cells and thereby slowing neuroinflammation,¹²² protecting against BBB breakdown,¹²³ reducing $\text{A}\beta$ production,^{124,125} and $\text{A}\beta$ neurotoxicity.¹²⁶ However, AD is without a remedy despite the various beneficial effects of AChEIs and memantine and the laborious efforts of trying to find a cure. Therefore, the importance of research aimed at identifying the underlying AD mechanisms, which could yield new pharmaceutical targets, cannot be exaggerated.

Significance of CAMs in potential treatment strategies

In light of the reported involvement of CAMs in the various aspects of AD, these molecules may offer new unexplored

treatment opportunities and when used as biomarkers that can provide potential tools to enable the clinical monitoring of AD related inflammation and cerebrovascular complications, disease progression, and treatment response. Depending on the overall treatment goal – prevention, disease-modification, or cure – different aspects of AD may need to be targeted.

Strategies to counteract neuroinflammation

In investigations of long-term use of anti-inflammatory agents, nonsteroidal anti-inflammatory drugs (NSAIDs) have shown beneficial effects in terms of reducing the risk of developing AD.¹²⁷ Moreover, long-term treatment responses to cholinesterase inhibitors were better in individuals treated with NSAIDs.¹²⁸ However, recently published extended results of the AD anti-inflammatory prevention trial (ADAPT) demonstrated that treatment with NSAIDs might have an adverse effect in the later stages of AD,¹²⁹ which indicates that inflammatory processes might shift from acute to chronic, meaning different pathways may be engaged. Anti-selectin substances have been suggested as another potential treatment to control inflammatory disease. However, similar to NSAID treatment, the timing of treatment may be of crucial importance.¹³⁰ Finally, due to the significant association between inflammatory events, AD pathology,^{131,132} and increased levels of ICAM-1, it is necessary to emphasize the importance of evaluating the various roles of the soluble and membrane-bound forms of ICAM-1. Targeting ICAM-1 in animal models of reperfusion injuries demonstrated a neuroprotective effect of anti-ICAM administration.^{133,134} In addition, ICAM-1 levels in cognitively conserved elderly patients have been linked to decreased parietal blood flow.¹³⁵ Therefore, the elucidation of altered ICAM-1 expression as a consequence or disease modifying component may identify this molecule as a potential target for future anti-inflammatory AD treatment options.

Strategies aimed at altering $\text{A}\beta$ metabolism

One of the reported effects of the AChEI rivastigmine is the modulation of secretase activity, which results in decreased $\text{A}\beta$ secretion.¹³⁶ Therefore, interference with the proteolytic generation of the $\text{A}\beta$ peptide by inhibition of β -secretase and γ -secretase activity could prove beneficial. However, β and γ -secretase inhibitors, as well as γ -secretase modulators, are yet to prove successful in clinical trials.¹³⁷ An alternative approach could be to target competition for secretase

activity by taking advantage of certain mechanisms such as the recruitment of presenilin to the cadherin-catenin complex at the expense of presenilin/ γ -secretase cleavage of APP.⁵⁹

Elimination of already deposited A β is another strategy for eradicating A β toxicity. For this purpose, both active and passive immunization against A β have been evaluated. The administration of pre-aggregated or soluble A β generated an antibody response and A β plaque reduction in aged animals. However, due to serious adverse effects with aseptic meningoencephalitis caused by T-cell activation in a subset of patients,¹³⁸ the initial clinical trial was interrupted. A new generation of active A β immunization using A β fragments, without the ability to activate T-cells, has currently entered Phase I trials.¹³⁷ An anti-CAM treatment could be useful to circumvent adverse immunization effects such as the influx of leukocytes into the CNS. Lessons learned from the field of MS research, including its animal model experimental autoimmune encephalomyelitis (EAE), suggest anti-integrin (α 4) treatment as a measure of preventing leukocyte influx.¹³⁹ Passive immunization strategies using humanized monoclonal antibodies directed against different sites of A β have shown improved cognitive functions in APOE carriers as well as reduced brain atrophy in APOE non-carrier in Phase II trials. Moreover, intravenously delivered immunoglobulins isolated from pooled human blood (IVIgs) were found to significantly reduce both A β plaques and inflammatory events in AD patients.¹³⁷

Enhanced A β clearance can also be achieved via targeted gene delivery by use of CAM-dependent transendothelial migration. For instance, a recent study convincingly showed that endogenous CD11b+ bone marrow cells home to A β plaques in the brain of AD transgenic mice. The study further demonstrated that subcutaneous infusion of CD11b+ bone marrow cells transfected with the gene coding for neprilysin, an A β -degrading enzyme, and completely arrested A β deposition.¹⁴⁰ Therefore, using CAM-dependent mechanisms to introduce cells harboring the appropriate genes into the CNS has large-scale potential.

Strategies targeting vascular alterations

Given the reported association between vascular risk factors and AD,²⁹ it is worth noting that activation of different platelet populations, which is also linked to vascular alterations and stroke,¹⁴¹ appears also related to AD¹¹⁰ and altered APP metabolism.¹⁰⁷ Since the activation of platelets involves alterations in P-selectin expression¹⁴² as well as integrin α IIb β complex activation,¹⁴² and since these molecules possibly regulate inflammatory processes,¹¹² which are known

to affect the vasculature, it is necessary to perform intensified studies that elucidate the potential of targeting platelet adhesion molecules in AD.

Conclusion

This review summarized current knowledge of CAMs associated with AD, as well as the potential clinical utility of CAMs as disease biomarkers or pharmaceutical targets in novel AD treatment strategies. It has also identified a major need for both experimental and clinical studies to characterize the specific mechanisms by which CAMs relate to AD. Numerous observational studies have reported altered levels of CAMs in AD, but the specific roles of CAMs as markers or mediators of biological events leading to cognitive deterioration and dementia remain undetermined.

Degenerative Neurological and Neuromuscular Disease

Publish your work in this journal

Degenerative Neurological and Neuromuscular Disease is an international, peer-reviewed, open access journal focusing on research into degenerative neurological and neuromuscular disease, identification of therapeutic targets and the optimal use of preventative and integrated treatment interventions to achieve improved outcomes, enhanced

survival and quality of life for the patient. The manuscript management system is completely online and includes a very quick and fair peer-review system. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <http://www.dovepress.com/degenerative-neurological-and-neuromuscular-disease-journal>
