Background: Severity of chronic rhinosinusitis (CRS), measured by disease-specific health-related quality-of-life questionnaires, is expected to increase in patients who also suffer from posttraumatic stress disorder (PTSD). Altered pain perception, sleep disorders, and fatigue may be associated with this comorbidity.

Methods: Severity of CRS was compared between a group of 28 patients with CRS and a group of 28 patients with CRS and concomitant PTSD using different disease-specific and generic instruments, such as visual analog scale (VAS), Short Form-36 test (SF-36), and Sino-Nasal Outcome Test-22 (SNOT 22).

Results: SNOT-22 test showed significantly higher CRS severity in patients with CRS and PTSD, compared to patients with CRS without PTSD.

Conclusion: Patients with less severe CRS, measured by objective outcome measures, due to the impact of comorbid PTSD, are classified as having severe rhinosinusitis, and are exposed to the risk of unnecessary diagnostic and therapeutic procedures. In patients with difficult-to-treat rhinosinusitis, diagnosis should be revised, and one item that should be evaluated is whether they suffer from PTSD.

Keywords: posttraumatic stress disorder, chronic rhinosinusitis, quality of life

Introduction

Chronic rhinosinusitis and posttraumatic stress disorder are diseases that strongly impact the quality of a person’s life.1,2 The etiology of chronic rhinosinusitis is multifactorial, with different inflammatory mechanisms that can lead to the development of the disease. The pathophysiology of the disease is intertwined, with numerous predisposing factors such as allergies, nonallergic hyperactivity, asthma, ciliary dyskinesia, and anatomic deformations.3

Diagnosis of rhinosinusitis has been made on the basis of recommendations found in the European Position on Rhinosinusitis and Nasal Polyps. The criteria are that the disease should last for more than 12 weeks with the existence of two or more symptoms, of which one has to be nasal blockage/congestion/obstruction or nasal/postnasal discharge. Other possible symptoms include facial pain or pressure and the reduction or loss of smell. The distinction between chronic rhinosinusitis without nasal polyps and chronic rhinosinusitis with nasal polyps is used to further point out differences in the pathophysiology and treatment of these two entities.3

Posttraumatic stress disorder is characterized by persistent and nonremitting psychologically distressing reactions to a prior traumatic event. There are three
main symptom clusters of posttraumatic stress disorder: (1) persistent re-experience of the event in a distressing way; (2) persistent avoidance of stimuli that remind one of the event; and (3) increased emotional arousal. It is assumed that a disorder in the synthesis of neurotransmitters in the hippocampus and amygdala contributes to the pathoanatomic background of the aforementioned symptoms.

The majority of patients in Croatia who are diagnosed with posttraumatic stress disorder are diagnosed with combat-related posttraumatic stress disorder, and the majority of these patients are men. Combat-related posttraumatic stress disorder is a clinically more severe disease than posttraumatic stress disorder caused by other forms of trauma. Given that both diseases are frequent in Croatia and other developed countries, the expected comorbidity of posttraumatic stress disorder and chronic rhinosinusitis is great.

Our hypothesis is that since patients who suffer from posttraumatic stress disorder and chronic rhinosinusitis simultaneously exhibit intense and widespread chronic pain, sleeping disorders, and fatigue, an additional deterioration of chronic rhinosinusitis symptoms occurs. The consequences of this are twofold: first, patients with the mild form of chronic rhinosinusitis are categorized into a group of patients with severe chronic rhinosinusitis, which exposes them to the risk of additional yet unnecessary therapies and diagnostic procedures; and second, with patients that do not react to the treatments, their diagnosis needs to be reviewed, and one of the differential diagnoses is posttraumatic stress disorder.

**Materials and methods**

**Patients**

The first group of patients was comprised of 28 males, whose chronic rhinosinusitis and posttraumatic stress disorder diagnosis had been confirmed. These patients had been hospitalized and treated in group therapy at the psychiatric ward of the County Hospital Virovitica in October 2010. They were all diagnosed with combat-related posttraumatic stress disorder. The second group was comprised of 28 male patients suffering from chronic rhinosinusitis alone, who were treated in the County Hospital Pakrac from June until October 2010. For all patients who were being treated for chronic rhinosinusitis and chronic rhinosinusitis/posttraumatic stress disorder, it is important to note that their diagnosis was based on the diagnostic criteria for chronic rhinosinusitis. This was confirmed by endoscopic results and computerized tomography scoring by Lund–Mackay, where the inclusion criterion was a score greater than 5 on this measure. Respondents that were included in the study did not suffer from other diseases. Both groups completed the Short Form-36 (SF-36), the Sino-Nasal Outcome Test-22 (SNOT-22), and visual analog scale (VAS) questionnaires.

**SF-36**

The SF-36 questionnaire measures patients’ general health status and contains 36 questions that represent eight health concepts by grouping into subgroups, and each question is asked independently. Subgroups include physical functioning, role-physical, bodily pain, general health, vitality, social functioning, role-emotional, and mental health. One question that was observed independently relates to the change of the patient’s health status in the year preceding the study, while the questions in the subgroups refer to the patient’s status within the previous month. We used a Croatian version of the SF-36. Results are expressed as percentages, and the average total noted among the general Croatian population is 61.62%.

**VAS**

The VAS questionnaire serves to evaluate the total severity of sinonasal symptoms, and the patient is asked to evaluate 18 questions, of which 12 are related to these symptoms, while the remaining six are related to general symptoms. The main question related to the patients’ symptoms is: “What is the extent of problems related to the symptom at the moment?” Sinonasal symptoms include headaches, nose congestion, runny nose, secretion from the nose into the throat, feeling of fullness in the face, face pain, toothache, tearing, coughing, nose bleeds, and crusts in the nose. The remaining symptoms include general health, fatigue, fever, nausea, vomiting, and diarrhea-like stools. Patients identified problems according to the VAS, and possible scores ranged from 0 to 10.

**SNOT-22**

The SNOT-22 is a validated patient self-report measure of symptom severity and health-related quality of life in sinonasal conditions. The SNOT-22 test has 22 questions, and patients have to choose up to five important items that have affected their lives. Results of all questions are summed up, with higher results indicating greater problems; it should be noted that the maximum possible score is 110 points. Results for the general population fall around 30 points. We also observed the test by dividing it into two subscales. The first subscale covered physical symptoms that were...
related to “nasal problems;” these questions went as far as question 12. The second subscale covered health-related quality of life, including “emotional, fatigue, and sleep symptoms,” and these included questions 13 to 22.10

Results and analysis

Statistical analysis

We tested group differences with the Mann–Whitney U test, and considered P < 0.05 to be statistically significant. Data were tabulated in a Microsoft Excel (Microsoft Corporation, Redmond, WA) spreadsheet and imported into the Statistical Package for the Social Sciences (SPSS) version 10.0 (IBM Corporation, Armonk, NY).

All examined patients were males. The average age of respondents in the chronic rhinosinusitis group was 48.4 ± 6.55 years (range 38–61), while the average age of respondents in the posttraumatic stress disorder/chronic rhinosinusitis group was 45.3 ± 4.89 years (range 43–60).

VAS

In the case of VAS test scoring, a lower score indicates a better result. The total VAS score was better among the chronic rhinosinusitis group at 3.8 points (range 1.7–6.2), and the score for the posttraumatic stress disorder/chronic rhinosinusitis group was 5.6 points (range 3.2–10). The difference was statistically significant (P < 0.05).

SF-36

In the case of the SF-36 test, the higher the result, the better the patient’s general health. Results were better for the chronic rhinosinusitis group at a mean of 58.75%, while for the posttraumatic stress disorder/chronic rhinosinusitis group was 45.3 ± 4.89 years (range 43–60).

SNOT-22

In the case of SNOT-22 testing, a lower score is indicative of a better result. Better results were found among the chronic rhinosinusitis group. The mean SNOT-22 sum score was 48.80 in the chronic rhinosinusitis group (range 44–51) and 58.33 in the posttraumatic stress disorder/chronic rhinosinusitis group (range 37–84) (P < 0.05) (Figure 2).

In the chronic rhinosinusitis group, the two most important symptoms are runny nose and nasal obstructions, and in the chronic rhinosinusitis/posttraumatic stress disorder group, the most important symptoms are the difficulties experienced when falling asleep and waking up at night.

By dividing the SNOT-22 test after question 12, we created two subscales: the first being “emotional, fatigue, and sleep symptoms,” and the second being “nasal problems.” We compared what percentage of patients chose “five important terms which affected their lives” from the two aforementioned groups, and we observed that 38% of patients in the chronic rhinosinusitis/posttraumatic stress disorder group chose items that were solely related to “emotional, fatigue, and sleep symptoms,” 12% chose items related to “nasal problems” alone, and 50% chose both or none. In contrast, 39% of patients in the chronic rhinosinusitis group chose items related to “nasal problems” alone, 13% chose items related to “emotional, fatigue, and sleep symptoms” alone, and 48% chose both or none (Figure 3).

Discussion

Chronic rhinosinusitis has adverse effects on quality of life, just like diabetes or heart disease.11 In the USA, 15% of the population suffers from this condition, and it is responsible for 13 million visits to a physician and 2 million hospitalizations per year.12,13 As per research that investigated 361 Gulf War veterans upon their return home, the most
frequent diagnosis in head and neck diseases was chronic rhinosinusitis. Posttraumatic stress disorder is the fourth most frequent psychiatric diagnosis in the USA, affecting 10% of males and 18% of females. From the aforementioned data, it is apparent that the expected comorbidity of chronic rhinosinusitis and posttraumatic stress disorder is large.

Chronic rhinosinusitis is a disease that is diagnosed on the basis of subjective symptoms, which means that only anamnesis and clinical examination are needed as diagnostics. An objective method like computed tomography is widely accepted, but it is insufficient in monitoring a patient’s condition because it correlates poorly with subjective symptoms. The scoring of computed tomography results by Lund–Mackay provides the best correlation of computed tomography results and subjective sinonasal symptoms; however, this correlation is lost with nonnasal sinonasal symptoms. Objectivization is also possible according to endoscopic grading, which is widely accepted, but this is dependent on the physician’s subjective assessment. Due to these weaknesses in these objective methods, evaluation by subjective tests provides the most valuable information about the course of the disease, therapy success, and the effects of the disease on each patient’s quality of life.

Confusion in evaluating a patient’s condition is caused by the division of symptoms as either minor or major. Namely, the term “minor” speaks to the sensitivity and specificity of a certain symptom as a diagnostic criterion, and does not address its prevalence or severity. Contrary to popular opinion, minor symptoms of headache and facial pressure are not the leading symptoms of rhinosinusitis; rather, fatigue prevails at a rate of 84%. With the detailed diagnosis and treatment of patients with facial pain as the obstinate symptom, we most often remove chronic rhinosinusitis as the cause of pain, and reach a neurological diagnosis. Only recently was posttraumatic stress disorder’s effect on chronic orofacial pain identified. It has also been identified that males with posttraumatic stress disorder are not the only ones who exhibit intense chronic pain; their spouses also report experiencing pain, often in the form of headaches.

With patients who report fatigue, it should be taken into consideration that 46% of patients with chronic fatigue syndrome suffer from nonallergic chronic rhinosinusitis, and that 26% of patients with chronic rhinosinusitis suffer from chronic fatigue syndrome. The correlation of chronic rhinosinusitis and chronic fatigue syndrome is well researched. The deterioration of symptoms in comorbid conditions is interpreted as having systematic nociceptive dysfunction that is not conditioned by local inflammatory response in the sinonasal area; rather, this pain arises from the central nervous system and the opioid system of the posterior horns of the spinal cord.

Posttraumatic stress disorder and chronic fatigue syndrome symptoms are similar to those noted in many “wartime” syndromes (soldier’s heart, shellshock, Gulf War syndrome) and “peacetime” syndromes (fibromyalgia, somatization disorders, and multiple chemical sensitivities), and this correlation is the topic of much research. The similarities of the pathophysiological changes of posttraumatic stress disorders and chronic fatigue syndrome that are taking place in the central nervous system (particularly in the amygdala and hypothalamus), point to the great potential of future research about the correlation of posttraumatic stress disorder and chronic rhinosinusitis, among other things. This is because posttraumatic stress disorder is much more frequent in the general population than chronic fatigue syndrome. All three questionnaires that we used in our study have shown that posttraumatic stress disorder deteriorates the symptoms of chronic rhinosinusitis, which then classifies patients into the severe group. The VAS that we used was adjusted to assess a patient’s current condition. Results have proven to us that both groups are currently in the active phase of the disease.

Studies that have applied the SF-36 test to compare the quality of life of patients with chronic rhinosinusitis and of patients with other chronic diseases like lumbago, chronic heart failure, and obstructive pulmonary diseases have shown that patients with chronic rhinosinusitis have poorer social functioning and higher pain sensitivity than patients with the other conditions. The chronic rhinosinusitis group from our research reported experiencing lower qualities of life,
which generated poorer total test results (58.75%); this was compared to the quality of life of the general population in Croatia, which was considerably higher (61.62%).

The SNOT-22 test is a test that consolidates sinonasal symptoms and some general health symptoms. The SNOT-22 test is used for the purpose of tracking the success in treating chronic rhinosinusitis. What is noticeable is the tendency that nasal problems contribute to the deterioration of test scores in the group, while in the chronic rhinosinusitis/posttraumatic stress disorder group, test scores are affected by emotional problems, fatigue, and sleep (Figure 3). Significantly poorer results among the chronic rhinosinusitis/posttraumatic stress disorder group point to a need for cooperation between the psychiatrist and otorhinolaryngologist when treating chronic rhinosinusitis because the deterioration of symptoms of rhinosinusitis, particularly without objective indicators, can be caused by the deterioration of posttraumatic stress disorder. By keeping this fact in mind, we can not only save the patient from additional pharmacological treatments, especially to reduce the pain, but we can also save patients from unnecessary surgeries. Operated patients with chronic rhinosinusitis/posttraumatic stress disorder can have poor or no postoperative recovery, which is frustrating for the patient and the surgeon. The problem can be looked at from another angle: in the case of patients with obdurate chronic rhinosinusitis symptomatology and/or poor postoperative recovery, the diagnosis needs to be reviewed and posttraumatic stress disorder must be taken into consideration as a potential comorbidity.

Conclusion
Higher chronic pain sensitivity, sleeping disorders, and tiredness in chronic rhinosinusitis/posttraumatic stress disorder patients aggravate the scores of chronic rhinosinusitis; therefore, these patients are classified as belonging to a group with severe rhinosinusitis. Patients with chronic rhinosinusitis that do not show signs of improvement with therapy may have comorbid posttraumatic stress disorder.
