Background: A retrospective utilization study was performed to evaluate utilization patterns for enteral nutrition in a university teaching hospital.

Methods: Enteral nutrition was divided into three types according to the nitrogen source, i.e., total protein type [Nutrison Fibre®, Fresubin Energy Fibre®, Fresubin®, Supportan® (a special immunonutrition for cancer patients or patients with increased demands for omega-3 fatty acids), Fresubin Diabetes® (a diabetes-specific formula), Ensure®]; short peptide type (Peptison®); and amino acid type (Vivonex®, Fresubin). A pharmacoeconomic analysis was done based on defined daily dose methodology.

Results: Among hospitalized patients taking enteral nutrition, 34.8% received enteral nutrition alone, 30% concomitantly received parenteral nutrition, and 35.2% received enteral nutrition after parenteral nutrition. Combined use of the different formulas was observed in almost all hospitalized patients receiving enteral nutrition. In total, 61.5% of patients received triple therapy with Nutrison Fibre, Fresubin Diabetes, and Supportan. Number of defined daily doses (total dose consumed/defined daily dose, also called DDDs) of formulas in descending order were as follows: Nutrison Fibre, Fresubin Energy Fibre, Fresubin Diabetes > Supportan > Peptison, Ensure > Vivonex, Fresubin. The ratio of the cumulative DDDs for the three types of enteral nutrition was 35:2.8:1 (total protein type to short peptide type to amino acid type). Off-label use of Fresubin Diabetes was also observed, with most of this formula being prescribed for patients with stress hyperglycemia. Only 2.1% of cancer patients received Supportan. There were 35 cases of near misses in dispensing look-alike or sound-alike enteral nutrition formulas, and one adverse drug reaction in an elderly malnourished patient who did not receive vitamin K1-enriched enteral nutrition during treatment with cefoperazone. After 4 months of the trial intervention, off-label use of Fresubin Diabetes was no longer endorsed by the Drug and Therapeutics Committee for nondiabetic patients, and the proportion of this formula prescribed for patients with stress hyperglycemia decreased by 20%, with a 10-fold increase in the amount of Supportan prescribed for cancer patients. Near misses in dispensing look-alike or sound-alike enteral nutrition were successfully abolished, and no severe coagulation disorders occurred after prophylactic administration of vitamin K1-enriched enteral nutrition in elderly malnourished patients receiving cefoperazone.

Conclusion: This utilization study indicates that continuous quality improvement is necessary and that a Drug and Therapeutics Committee can play an important role in promoting rational and safe use of enteral nutrition. Appropriateness of this therapy still needs to be improved, especially in addressing the issues of non-evidence-based combined use of multiple enteral nutrition formulas, the relatively high rate of concomitant use of enteral and parenteral nutrition, off-label use of diabetes-specific Fresubin Diabetes, insufficient use of Supportan in cancer patients, and unnecessary use of Supportan in intensive care patients not suffering from cancer.

Keywords: enteral nutrition, drug utilization, indications, parenteral nutrition, pharmacoeconomics, rational drug use
Introduction

Compared with parenteral nutrition, enteral nutrition is less expensive and has fewer complications. If the gut works, enteral nutrition is preferred. Compared with parenteral nutrition, the cost savings associated with reduction in risk of adverse events and decrease in duration of hospital stay using enteral nutrition average nearly $4000 per patient in the US. Shifting 10% of adult patients from enteral nutrition to parenteral nutrition will save $35 million annually.

Enteral nutrition formulas can be divided into three categories according to the nitrogen source, ie, total protein type, short peptide type, and amino acid type. Inappropriate ordering of enteral nutrition by physicians leads to unnecessary financial expense and decreased therapeutic efficacy, as well as an increased likelihood of adverse events. Therefore, it is necessary to be able to identify and monitor current prescribing patterns for enteral nutrition. However, no literature on enteral nutrition utilization patterns, especially the different types of enteral nutrition, was identifiable on the PubMed database. Therefore, we examined clinical risks and prescribing practices for enteral nutrition in hospitalized patients in a large university teaching hospital and investigated whether the three types of enteral nutrition were prescribed appropriately based on formula characteristics and patient disease status.

Materials and methods

Data collection

This retrospective drug utilization study was performed in a tertiary university teaching hospital with 2200 beds. Data were obtained from the hospital information system and processed using Visual FoxPro version 9.0. Records of new or serious adverse events, and near misses associated with enteral nutrition, were audited retrospectively.

Eight enteral nutrition formulas were included: total protein type (Nutrison Fibre®, Fresubin Energy Fibre®, Fresubin®, Supportan® (a special immunoenhancing formula for cancer patients or those with increased demands for omega-3 fatty acids), Fresubin Diabetes® (a diabetes-specific formula), Ensure®); short peptide type (Peptison®); and amino acid type (Vivonex®). The nutritional components of these formulas are shown in Table 1.

Statistical analysis

A descriptive analysis was performed on all prescriptions of enteral nutrition for patients hospitalized in 2011. A defined daily dose (DDD) methodology was used. The defined daily doses for enteral nutrition were derived from package inserts and calculated based on the daily dose of nutritional supplements. Number of defined daily doses (also called DDDs) and daily expenditure were estimated using the following equations:

$$\text{DDDs} = \frac{\text{Total dose consumed}}{\text{DDD}}$$

$$\text{Daily expenditure} = \frac{\text{Overall expenditure}}{\text{DDDs}}$$

Differences between patient groups were tested for statistical significance using the Student’s t-test. A P value < 0.05 was considered to be statistically significant.

Results

Combination use

There were 2928 hospitalized patients taking enteral nutrition in 2011. Of these, 1020 (34.8%) received enteral nutrition alone, 878 (30%) patients received concomitant parenteral nutrition, and 1030 (35.2%) received enteral nutrition following parenteral nutrition. The difference in age between patients receiving enteral nutrition alone and those receiving enteral and parenteral nutrition was not statistically significant (P > 0.05). The parenteral nutrition therapies were categorized according to energy and substitutes, ie, normal, high stress, and fluid-restricted. A team consisting of specialized doctors, nurses, clinical pharmacists, and dietitians assessed each patient’s clinical status and decided on which parenteral nutrition formula to use. On average, 160 bags of parenteral nutrition mixtures were prescribed, most of which consisted of glucose, amino acids, lipids, water, electrolytes, essential vitamins, minerals, and trace elements. About 60 three-chamber bags of standard parenteral nutrition-based mixtures (Kabiven®, Fresenius Kabi AB, Sweden) were used in intensive care units every day.

Combination use of multiple formulas was documented in 99.7% of hospitalized patients receiving enteral nutrition (Table 2). The relative percentage of different combination modes was as follows: triple therapy (72.7%) > dual therapy (24.8%) > quadruple therapy (2.2%). The age difference between patients on monotherapy, dual therapy, triple therapy, and quadruple therapy with different enteral nutrition formulas was not statistically significant (P > 0.05). Surprisingly, 61.5% of patients on enteral nutrition received triple therapy of Nutrison Fibre, Fresubin Diabetes, and Supportan.

Pharmacoeconomic data

Pharmacoeconomic data for the eight enteral nutrition formulas are shown in Table 3. The values of DDDs in
descending order were: Nutrison Fibre, Fresubin Energy Fibre, and Fresubin Diabetes > Supportan > Peptison, and Ensure > Vivonex and Fresubin. The ratio of cumulative DDDs for the three types of enteral nutrition was 35:2.8:1 (total protein type to short peptide type to amino acid type), and the order of daily expenditure was: Vivonex, Peptison, Supportan, Fresubin Diabetes, Fresubin Energy Fibre, and Fresubin Ensure.

Enteral nutrition according to ward type
Nutrison Fibre and Fresubin Energy Fibre were prescribed more frequently in intensive care, burns, neurology, and neurosurgery wards than in other wards (80% versus 20%). Off-label use of Fresubin Diabetes was commonly observed. Of 331 patients receiving this formula, only four (1.2%) patients suffered from diabetes. Most of this formula was prescribed for patients with potential stress hyperglycemia. The amount of Supportan consumed in oncology wards with 9600 person-time inpatients annually accounted for 6.9% of total consumption of this formula in this hospital. Only 2.1% of cancer patients received Supportan. Seven of the enteral nutrition formulas (ie, Nutrison Fibre, Fresubin Energy Fibre, Supportan, Fresubin Diabetes, Ensure, Peptison, and Vivonex) were prescribed more frequently in intensive care wards than in non-intensive care wards. Consumption in intensive care as a proportion of total consumption in all wards was: 57.0% (Nutrison Fibre), 47.5% (Fresubin Energy Fibre), 37.9% (Supportan), 53.5% (Fresubin Diabetes), 20.7% (Ensure), 54.9% (Peptison), and 74.7% (Vivonex).

The top seven wards using the enteral nutrition formulas, based on cumulative DDDs, in intensive care accounted for 48.7% of the sum of DDDs for all enteral nutrition formulas in this hospital. Relative percentages for the other six wards were: geriatrics (11.3%), burns (10.5%), neurology and neurosurgery (9.7%), general surgery (6.0%), thoracic surgery (2.5%), and oncology (2.0%).

Near misses and adverse events
In 2011, there were 35 cases of near misses when dispensing look-alike or sound-alike formulas of enteral nutrition. Fortunately, all these near misses made by pharmacists were detected and reported by clinical nurses.

Except for mild diarrhea, new or serious adverse events attributable to enteral nutrition were not detected.

In 2011, there were 35 cases of near misses when dispensing look-alike or sound-alike formulas of enteral nutrition. Fortunately, all these near misses made by pharmacists were detected and reported by clinical nurses.

Except for mild diarrhea, new or serious adverse events attributable to enteral nutrition were not detected.
in 2011. However, there was one case of an adverse drug reaction in an elderly malnourished patient not receiving vitamin K1-enriched enteral nutrition during treatment with cefoperazone. This was a 98-year-old bedridden tube-fed patient with an acute bacterial exacerbation of chronic bronchitis and cerebrovascular disease and suffering from a severe coagulation disorder induced by cefoperazone. A consultation was requested with a clinical pharmacist who identified that the cause of this adverse event was vitamin K deficiency caused by eradication of vitamin K-producing intestinal bacteria or inhibition of action of vitamin K1 as a result of enteral nutrition given without vitamin K supplementation. The coagulopathy was corrected by administration of vitamin K1, cessation of the antibiotic, and addition of vitamin K1-enriched high-density Nutrison Fibre (20 µg/500 mL). Prophylactic administration of vitamin K1 is now recommended for all elderly malnourished patients being treated with cefoperazone in this hospital.

Preliminary intervention efforts
The appropriateness of enteral nutrition attracted the attention of the Drug and Therapeutics Committee at our hospital in February 2012. A Plan-Do-Check-Act cycle was used for continuous quality improvement. After 4 months of this preliminary intervention, off-label use of Fresubin Diabetes was no longer approved by the Drug and Therapeutics Committee for nondiabetic patients, and the amount of this formula prescribed for patients with stress hyperglycemia decreased by 20%. There was also a 10-fold increase in the amount of Supportan prescribed for cancer patients. Near misses in dispensing of look-alike or sound-alike enteral nutrition were successfully abolished, and no cases of cefoperazone-induced severe coagulation disorder occurred when prophylactic vitamin K1-enriched enteral nutrition was administered to elderly malnourished patients receiving cefoperazone.

Discussion
Combination of enteral and parenteral nutrition
Clinical studies have shown that a combination of enteral and parenteral nutrition can improve the clinical outcome in intensive care patients, including reducing morbidity, length of stay, and recovery time, as well as improving quality of life and decreasing health care costs. A meta-analysis has shown that 80% of critically ill patients can receive enteral nutrition alone, 10% can receive combined enteral and parenteral nutrition, and the remaining 10% need total parenteral nutrition. Our survey indicated that one-third of patients received combined enteral and parenteral nutrition. The relatively high rate of combination use of parenteral and enteral nutrition suggests that enteral nutrition alone may be inadequate.

No evidence for combined use of multiple enteral nutrition formulas is available in the PubMed database, so further investigations addressing this issue need to be performed. Triple therapy with one bottle each of Nutrison Fibre, Fresubin Diabetes, and Supportan costs about 600 Chinese Yuan Renminbi (CNY) per day and was considered to be overuse of medication, the underlying reasons for which are unclear. A pharmacoeconomic study on this issue needs to be performed in the future.

Pharmacoeconomic indices
The DDDs indicates trends in drug use, such that the higher DDDs of a therapy, the more frequent its utilization. In our study, the DDDs for Nutrison Fibre and Fresubin Energy Fibre ranked first and second, respectively, which may be due to the characteristics of the two formulas, ie, their
high energy density (1.5 kCal/mL), high protein content (56–60 g/1000 mL), and amount of added dietary fiber (15–20 g/1000 mL). Peptison and Vivonex were found to have markedly lower DDDs compared with total protein type enteral nutrition, which may be attributed to the higher price and defined daily doses of these two formulas. The ratio of cumulative DDDs for the three types of enteral nutrition was 35:2.8:1 (total protein type to short peptide to amino acid type), reflecting formula characteristics. To our knowledge, ours is the first report of enteral nutrition consumption in clinical practice.

**Enteral nutrition consumption according to type of ward**

Table 4 summarizes the strengths and shortcomings of each of the eight enteral nutrition formulas investigated in this study. Nutrison Fibre and Fresubin Energy Fibre are concentrated formulas, and more suitable for patients who require water restriction because of brain injury or heart failure, as well as for patients with high energy and protein demands. Intensive care, burns, neurology, and neurosurgery wards accounted for about 80% of total consumption of Nutrison Fibre and Fresubin Energy Fibre. This utilization pattern may also reflect the characteristics of the two formulas.

Fresubin Diabetes is a diabetes-specific formula, as described in its package insert. It can reduce glucose load in patients with diabetes or glucose intolerance. Intensive care, geriatrics, and burns wards accounted for 80% of total consumption of Fresubin Diabetes. A literature review did not find evidence of off-label use of this formula (ie, for prevention of potential stress hyperglycemia). Although well controlled studies have demonstrated that hyperglycemia is an indicator of poor clinical outcome in inpatients, further studies are needed to determine whether Fresubin Diabetes helps to improve glycemic control.

Supportan is a high-fat, high-energy density, low carbohydrate formula which is designed based on the metabolic characteristics of tumor cells. (ie, a high glucose demand compared with benign cells of the same tissue) and is thus specific for cancer patients with malnutrition. It is also indicated for patients with an increased demand for omega-3 fatty acids. Our survey found that only 2.1% of cancer patients received Supportan, and the amount of this formula consumed in oncology wards accounted for only 2% of the total amount consumed in our hospital. Cumulative DDDs of all enteral nutrition formulas in oncology wards accounted for only 2% of the cumulative DDDs of the eight enteral nutrition formulas in all wards. The prescribing patterns for Supportan as well as other enteral nutrition formulas in the oncology wards indicated inadequate awareness of clinical nutrition support for cancer patients.

Consumption of Supportan in the intensive care setting accounted for 37.9% of total consumption by all wards, which may reflect the beneficial effects of omega-3 fatty acids in critically ill patients, ie, a reduced incidence of complications and shorter hospitalization times. However, more research is needed before definitive recommendations can be made concerning the routine use of omega-3 fatty acids in critically ill patients. Further, Nutrison Fibre contained a higher defined daily dose-based quantity of omega-3 fatty acids (4.1 g versus 3.6 g) and was less expensive than Supportan (212.5 CNY versus 345 CNY, respectively). Therefore, routine use of Supportan in intensive care patients is not a cost-effective option, and doctors need to consider medication costs when prescribing for patients who do not have cancer.

Peptison is a peptide-based formula. Peptide-based enteral nutrition is easily used and more likely to improve nutritional status and immune function and thereby enhance postoperative recovery. The amount of Peptison consumed in intensive care and general surgery wards accounted for 54.9% and 17.7%, respectively, of the total amount consumed. Again, the prescribing pattern for Peptison reflects its characteristics. From the perspective of pharmacoeconomics, a total protein-based formula instead of a short peptide-based formula is the preferred choice for patients with normal or almost normal digestion and absorption in the gastrointestinal tract.

Vivonex is an amino acid-based formula and suitable for patients with severe metabolic disorders and gastrointestinal dysfunction. The amount of Vivonex consumed in intensive care accounted for 74.7% of the total amount consumed in the hospital, with the data yet again reflecting the characteristics of this formula.

Adequate nutritional support is important in the comprehensive management of patients in intensive care. Early administration of enteral nutrition maintains gastrointestinal integrity and function, thus minimizing the translocation of organisms, and reducing complication rates, length of stay in intensive care, and risk of death. American Society for Parenteral and Enteral Nutrition guidelines highlight enteral nutrition as the preferred route of feeding over parenteral nutrition in critically ill patients who require nutrition support, starting within the first 24–48 hours following admission to intensive care. The prescribing patterns
in intensive care in our survey indicate adequate enteral nutrition support.

Lam et al concluded that, in burns patients, early enteral nutrition had better effects than total parenteral nutrition on immune and metabolic function and reduces the rates of complications and mortality.\textsuperscript{13} Cumulative DDDs of all enteral nutrition formulas in the burns ward accounted for 10.5\% of the sum of DDDs for all enteral nutrition formulas in all wards, reflecting good awareness of the need for enteral nutrition support in burns patients.

Malnutrition is common both before and after stroke, with dysphagia adding to nutritional risk. Further, malnutrition leads to prolonged length of hospital stay, reduced functional status, and poorer survival. Early enteral nutrition...
supplements can significantly improve nutritional intake in undernourished stroke patients. The sum of DDDs for the eight enteral nutrition formulas consumed in the neurology ward ranked fourth. An enteral formula containing hydrolyzed whey protein can decrease inflammation and increase antioxidant defense in elderly patients with ischemic stroke to a greater extent than a standard enteral formula containing casein as the protein source. Whey protein-based enteral nutrition is superior to casein-based enteral nutrition for patients with stroke. However, hydrolyzed whey protein-enriched Peptison was prescribed far less often than casein-enriched Nutrison Fibre at our hospital, with the ratio of the DDDs for these two formulas being 15:1 (casein versus hydrolyzed whey protein). The daily expenditure on Peptison was nearly twice that of Nutrison Fibre, which may explain the utilization patterns seen for the two formulas in stroke patients.

Conclusion
In this study, clinical enteral nutrition utilization patterns were evaluated in a university teaching hospital. Generally, clinicians had good awareness of the need for nutrition support, with adequate use in intensive care, geriatrics, burns, neurology, and neurosurgery wards, and an appropriate ratio for use of the three different types of enteral nutrition in line with formula characteristics. However, ongoing quality improvement is necessary, in particular to address issues such as non-evidence-based combination use of multiple enteral nutrition formulas, a relatively high rate of concomitant use of enteral and parenteral nutrition, off-label use of diabetes-specific Fresubin Diabetes, insufficient use of Supportan in cancer patients, and the costly use of Supportan in intensive care patients without cancer.
