Abstract: The present study aimed to describe heart rate (HR) responses during a simulated Olympic boxing match and examine physiological parameters of boxing athletes. Ten highly trained Olympic boxing athletes (six men and four women) performed a maximal graded exercise test on a motorized treadmill to determine maximal oxygen uptake (52.2 mL ⋅ kg⁻¹ ⋅ min⁻¹ ± 7.2 mL ⋅ kg⁻¹ ⋅ min⁻¹) and ventilatory thresholds 1 and 2. Ventilatory thresholds 1 and 2 were used to classify the intensity of exercise based on respective HR during a boxing match. In addition, oxygen uptake (\(\dot{V}O_2\)) was estimated during the match based on the HR response and the HR-\(\dot{V}O_2\) relationship obtained from a maximal graded exercise test for each participant. On a separate day, participants performed a boxing match lasting three rounds, 2 minutes each, with a 1-minute recovery period between each round, during which HR was measured. In this context, HR and \(\dot{V}O_2\) were above ventilatory threshold 2 during 219.8 seconds ± 67.4 seconds. There was an increase in HR and \(\dot{V}O_2\) as a function of round (round 3 < round 2 < round 1, \(P < 0.0001\)). These findings may direct individual training programs for boxing practitioners and other athletes.

Keywords: heart rate, physiological profile, intermittent exercise, combat sports, boxing

Introduction

Boxing is a combat sport in which athletes try to strike and/or defend themselves from the attacks of their opponents. Matches are characterized by dynamic phases of short duration, which involve almost all muscle groups in complex movements characterized by short phases of maximal and/or supramaximal effort intensity, which lead to rapid accelerations and decelerations of body segments.1

To obtain an understanding of the physiological capacities underlying boxing performance, it would be useful to know the cardiovascular demand and the degree of recruitment of anaerobic metabolism during a match. These physiological variables would provide benchmarks for improving and monitoring athlete training regimens.2,3 In addition, it could provide a basis for athletic performance strategies, as it would enable one to identify an athlete’s potentials and limitations.4 Heart rate (HR) monitoring offers the opportunity to directly and easily evaluate the physiological profile of discipline-specific performance and inexpensively evaluate the physiological demands.5 However, few studies in the literature have reported on the physiological demands of combat sports.1,6-9 In this context, maximal graded exercise testing is commonly employed to determine physiological response to exercise. Maximum oxygen uptake (\(\dot{V}O_2\) max) of an individual, which serves as a good marker for aerobic fitness, can be achieved during an exhaustive exercise test. Furthermore, graded maximal exercise testing allows for
the determination of ventilatory thresholds (first ventilatory threshold [VT₁] and second ventilatory threshold [VT₂]). VT₁ corresponds to the break point in the plot of carbon dioxide production (\(\dot{V}CO₂\)) as a function of oxygen uptake (\(\dot{V}O₂\)). At that point, the ventilatory equivalent for \(O₂ (\dot{V}E/\dot{V}O₂)\) increases without an increase in the ventilatory equivalent for \(CO₂ (\dot{V}E/\dot{V}CO₂)\). VT₂ is located between VT₁ and \(\dot{V}O₂\) max, when \(\dot{V}E/\dot{V}CO₂\) starts to increase as \(\dot{V}E/\dot{V}O₂\) continues to increase. In practical terms, VT₁ and VT₂ can be used to prescribe exercise and to classify exercise intensity.

Because the popularity of combat sports practice is increasing, research into the physiological profile of these sports is necessary. Therefore, the aims of this study were to investigate physiological parameters of amateur boxers and to describe HR responses during a simulated boxing match. Also, the study compared HR responses during a simulated boxing match with those of HR associated with VT₁ and VT₂ attained during a maximal graded exercise test.

**Methods**

**Participants**

Ten highly trained boxing athletes (six men [two junior and four senior] and four women [two junior and two senior]) were recruited from local boxing teams located in São Paulo, Brazil. The age and anthropometrical characteristics of the participants are presented in Table 1. Each participant's height and weight were measured to the nearest 0.1 cm and 0.1 kg, respectively. Skinfold thicknesses were obtained to estimate body fat percentage. Skinfold measurements were taken from seven sites on the right side of the body: triceps, subcapular, suprailliac, chest, abdomen, thigh, and midaxillary using a Lange skinfold caliper (Cambridge Scientific Industries, Inc, MD, USA). All skinfold measurements were carried out by the same examiner (to avoid inter examiner variability), who was previously trained and experienced in the use of skinfold calipers. Duplicate measurements were obtained, and the mean recorded value was used to determine body density.¹² The Jackson and Pollock equation¹³ was used for male athletes, and the equation formulated by Jackson et al¹⁴ was used for the female athletes. Body density values were then converted to body fat percentage using the Siri equations.¹⁵

All athletes trained five times a week in 2.5 hour sessions and had accumulated more than 2 years of training and competition. Their training focused on the development of technical and tactical skills that were specific to the sport of boxing and on the improvement of match-related fitness. All experimental procedures were approved by the University Human Research Ethics Committee and conformed to the principles outlined in the Declaration of Helsinki. All participants signed informed consent forms prior to participating in the study. For those participants under 18 years of age, written informed consent was signed by parents or guardians. All athletes were highly motivated to participate in the study and familiar with all testing methods. Participants continued their regular training programs and were requested, with their coaches consent, to refrain from strenuous workouts on the day before the test.

**Baseline medical examinations**

Before the beginning of the experimental procedures, each participant came to the laboratory for anamnesis and a physical examination to assess their health. These tests did not reveal any abnormalities that could contraindicate the participants’ inclusion in the study.

**Experimental procedures**

Each participant reported to the laboratory on two separate occasions. During the first session, a maximal graded exercise test was administrated to determine VT₁, VT₂, and \(\dot{V}O₂\) max, as well as their associated running velocities and HR. In the second visit to the laboratory, the participants performed a simulated boxing match. A period of at least 48 hours separated the two laboratory visits, and all experimental procedures were completed within a 2-week period. All participants were instructed to refrain from eating 2 hours before laboratory visits and to abstain from caffeine, alcohol, and strenuous physical activity on each test day. Water intake was allowed ad libitum. The temperature and relative humidity in the testing laboratory ranged from 21°C–23°C and 55%–65%, respectively, for all trials. We carried out our experiments in both the morning and afternoon. However, for each participant, the maximal graded exercise test and simulated boxing match were conducted at the same time of day.

Prior to performing the maximal graded exercise test, participants were given a standardized set of instructions.

explaining the test. On completion of these preliminary procedures, each participant underwent an incremental maximal exercise test on a motorized treadmill (Super ATL, Inbrasport Ltd, São Geraldo, MG, Brazil) with 0% slope. The schedule of this test consisted of a 5-minute warm-up period at 6 km·h⁻¹, and then the initial speed was adjusted to 7 km·h⁻¹, followed by progressive increases of the treadmill speed at a rate of 1 km·h⁻¹ every minute until participant exhaustion. During the exercise testing, participants were verbally encouraged to exercise for as long as possible. Respiratory gas samples of each breath were analyzed using a gas analyzer (K4b2, COSMED, Rome, Italy). Before each test, the gas analyzer was calibrated using gas of a known concentration (16% of O₂ and 4% of CO₂; White Martins, Rio de Janeiro, Brazil), and the flow meter was calibrated using a 3 L syringe (Hans Rudolph, Inc, Shawnee, KS, USA). A Polar Electronics HR monitor (Polar Electronics, FS1, Kempele, Oulu, Finland) was used to record in real-time, as the metabolic system utilized in this study was equipped with a receiver unit, able to capture the signal.

The following data (averaged over 20 seconds) were obtained: $\dot{V}O_2$ (mL·min⁻¹) at standard temperature (0°C) and barometric pressure at sea level, $\dot{V}CO_2$ (mL·min⁻¹) at standard temperature (0°C) and barometric pressure at sea level, respiratory exchange ratio (RER), minute ventilation $\dot{V}E$ (L·min⁻¹) at body temperature and pressure saturated, respiratory rate (breaths per minute [bpm]), ventilatory equivalents for O₂ and CO₂ ($\dot{V}E/\dot{V}O_2$ and $\dot{V}E/\dot{V}CO_2$, respectively), expired fractions of O₂ and CO₂ (%) and HR (beats per minute [bpm]). Peak treadmill velocity was defined as the last achieved running speed sustained for at least 30 seconds. $\dot{V}O_2$ max was always defined as the highest 20-second averaged $\dot{V}O_2$ value with inclusion criteria consistent with conventional guidelines for $\dot{V}O_2$ max (eg, an inability to sustain the workload, relative HR >95% predicted for their age, RER at maximal exercise >1.1, and $\dot{V}O_2$ plateau [the point at which $\dot{V}O_2$ increases less than 150 mL·min⁻¹ for a given increase in workload]). Ventilatory thresholds were assessed using established criteria.²⁴ Briefly, VT₁ corresponds to the break point in the plot of $\dot{V}CO_2$ as a function of $\dot{V}O_2$. At that point, $\dot{V}E/\dot{V}CO_2$ increases without an increase in $\dot{V}E/\dot{V}O_2$, VT₂ was located between VT₁ and $\dot{V}O_2$ max, when $\dot{V}E/\dot{V}CO_2$ starts to increase and $\dot{V}E/\dot{V}O_2$ continues to increase. VT₁ and VT₂ were determined independently by three experienced investigators. If agreement between two out of three investigators was not achieved, VT was determined by consensus. To determine the $\dot{V}O_2$ and $\dot{V}E$ at VT₁ and VT₂, the average of the last 20 seconds of each corresponding level was used. In practical terms, ventilatory thresholds represent points that can be used to classify the intensity of aerobic exercise.

Finally, the second visit to the laboratory was used to apply a simulation of a boxing match. This simulation was conducted in a boxing ring (6 m × 6 m) and was accompanied by a referee with extensive experience in boxing. The participants were instructed to prepare themselves as they usually would for an official match. Participants performed a 10 minute warm up, which consisted of standard boxing movements, and then rested on a bench until HR returned to the pre-exercise level. The match consisted of three rounds, each 2 minutes long, with 1 minute of recovery between them. During each recovery period, the participant sat on a bench and was allowed to drink water. To simulate a match as realistically as possible, a sparring partner with a skilled trainer was enlisted. This partner had the same body mass, height, sex, ability, and boxing experience as the evaluated athlete and was aware of his or her participation in a scientific study. Additionally, the athletes were verbally encouraged by their coaches throughout the match to perform as well as possible. After the 1 minute recovery period following the last round, an additional 10 minute period of further recovery was allowed (final recovery). HR was recorded before, during (including rest periods between rounds), and after the simulated boxing match. HR registers (5-s average HR value) were monitored by a commercially available telemetric system (Suunto Team Pod, Suunto, Vantaa, Finland), which allowed us to monitor heart rate in real time. HR recorded during a simulated boxing match was compared with HRs corresponding to VT₁ and VT₂. In addition, $\dot{V}O_2$ was estimated during the match for each participant based on the HR response and the HR-$\dot{V}O_2$ relationship for each participant as determined from maximal graded exercise test results. Despite the indirect $\dot{V}O_2$ estimation by HR-$\dot{V}O_2$ relationship obtained from maximal graded exercise test, this strategy is considered valid for intermittent activities.²⁷⁻²⁹

Statistical analysis

All variables presented normal distributions (P > 0.05) according to Kolmogorov–Smirnov tests. Therefore, the differences between rounds were analyzed by one-way ANOVA (analysis of variance) for repeated measures. When significant modifications were found, the Tukey post hoc procedure was performed to localize the difference. Pearson linear regression analysis was used to determine any potential linear relationships between variables. All statistical analyses were performed with GraphPad Prism 5.0 (San Diego, CA,
USA). The level of significance was $P < 0.05$. Data are shown as the means ± standard deviations.

## Results

Data for the maximal graded exercise test are shown in Table 2. All participants ($n = 10$) attained age-predicted maximum HR, RER > 1.1, fatigue and VO$_2$ plateau (when VO$_2$ increased less than 150 mL · min$^{-1}$ for a given increase in workload). The VO$_2$ max of the athletes was 52.2 mL · kg$^{-1} ·$ min$^{-1}$ ± 7.2 mL · kg$^{-1} ·$ min$^{-1}$ and was reached at a treadmill speed of 15.7 km · h$^{-1} ± 2.5$ km · h$^{-1}$, with a maximum heart rate (HR$_{\text{max}}$) of 193 bpm ± 7 bpm. VT$_1$ and VT$_2$ were detected in all cases. The VO$_2$ levels at VT$_1$ and VT$_2$ were 40.5 mL · kg$^{-1} ·$ min$^{-1} ± 5.9$ mL · kg$^{-1} ·$ min$^{-1}$ and 47.5 mL · kg$^{-1} ·$ min$^{-1} ± 6.0$ mL · kg$^{-1} ·$ min$^{-1}$, respectively, and were reached at treadmill speeds of 11.0 km · h$^{-1} ± 1.4$ km · h$^{-1}$ and 13.6 km · h$^{-1} ± 1.8$ km · h$^{-1}$, with HRs of 167 bpm ± 9 bpm and 181 bpm ± 6 bpm, respectively.

The HR behavior during the simulated boxing match is shown in Table 3. There was a round effect ($P < 0.0001$): the highest HR and percent of HR$_{\text{max}}$ were attained in round three and were 4.7% ($P = 0.0008$) and 5.5% ($P = 0.0009$) higher than those attained in round one, respectively. The average HR in round two and percent of HR$_{\text{max}}$ attained were both 4.5% ($P < 0.0001$ for both) higher than those attained in round one. The average HR in round three and the respective percent of HR$_{\text{max}}$ attained were 6.3% and 5.5% ($P < 0.0001$) for both higher than those attained in round one, respectively. In round one, the average time spent at a HR below the VT$_1$ level was 22.5 seconds ± 23.9 seconds, time spent at a HR between the VT$_1$ and VT$_2$ levels was 47.9 seconds ± 35.5 seconds, and time spent at a HR above the VT$_2$ level was 49.6 seconds ± 42.7 seconds. In round two, the average time spent below the VT$_2$ HR was 9.0 seconds ± 7.5 seconds, between the VT$_1$ and VT$_2$ HRs was 21.0 seconds ± 7.8 seconds and above the VT$_2$ HR was 90.0 seconds ± 12.9 seconds. In round three, the mean time spent below the VT$_1$ HR was 7.0 seconds ± 16.0 seconds and 5.6 seconds ± 13.0 seconds, between the VT$_1$ and VT$_2$ was 14.0 ± 6.0 and above the VT$_2$ was 99.0 seconds ± 14.0 seconds. It is noteworthy that there was a progressive decrease in the amount of time below the VT$_1$ HR and, consequently, a gradual increase of the time spent above the VT$_1$ HR. Similar behavior was found in estimated VO$_2$ during the simulated boxing match (Table 4).

There was a round effect for HR recovery ($P < 0.0001$): HR measured immediately at the end of the round was significantly different between rounds (Table 5) (round three > round two > round one). Regarding HR after 60 seconds of recovery, there was a significant difference only between round one and round two ($P = 0.0235$). HR recovery [Δ (%)] was 13%–19% for all rounds, without differences between them ($P = 0.1034$). In absolute values, the decrease in HR was 35 bpm ± 23 bpm, 26 bpm ± 11 bpm, and 32 bpm ± 13 bpm, respectively, for round one, round two, and round three, without differences between them ($P = 0.1229$).

There were no significant correlations between aerobic variables and Δ (%), VO$_2$ max and its Δ (%) ($r = 0.5432$ and $P = 0.1047$), VO$_2$ at VT$_1$ and its Δ (%) ($r = 0.5336$ and $P = 0.1122$), VO$_2$ at VT$_2$ and its Δ (%) ($r = 0.6307$ and $P = 0.0506$), VO$_2$ max and its Δ (%) ($r = 0.5227$ and $P = 0.1211$), VT$_1$ and its Δ (%) ($r = 0.5157$ and $P = 0.1271$) and VT$_2$ and its Δ (%) ($r = 0.5026$ and $P = 0.1387$) were all not correlated with HR recovery.

## Discussion

The primary aims of the present study were to describe the behavior of HR during a simulated Olympic boxing match and characterize the intensity of the modality and physiological profile of these athletes. The main finding of this descriptive study was that the average intensity of a simulated boxing match was very severe, as an appreciable percentage (~60%) of the exercise bout occurred at an intensity greater than VT$_1$, based on maximal HR (above 85% of the age-predicted maximal HR).

The findings of this study show that the percentage of the simulated boxing match at exercise intensities greater than VT$_1$ was much higher than routinely observed in athletes during spontaneous training, although it is within the range of individual high-intensity training bouts in athletes.

Wushu, Chito Ryu Seisan Kata, taekwondo, and Muay Thai are also combat sports that present elevated
intensities during matches. Bridge et al. 22-25 evaluated the HR responses of specific Taekwondo training activities practiced by experienced practitioners in a natural training environment and found that this sport stimulated the HR to reach 64.7%–81.4% of HR\textsubscript{max}. Therefore, boxing, as with other combat sports, has a strong impact on cardiovascular and respiratory functions.

However, as an episodic training activity, the comparatively high intensity may be associated with an effective training response. In particular, results presented by Helgerud et al. 26 and Laursen et al. 27 have suggested that improving VO\textsubscript{2} max in already trained athletes, required training intensities which approached the intensity of VO\textsubscript{2} max. This could be a plausible explanation for the high VO\textsubscript{2} max observed in our athletes. Other studies of boxing and various combat sports have found similar values of VO\textsubscript{2} max. 7,11,22

Another objective of the present study was to determine the aerobic physiological parameters of boxers. This is an important objective because the physiological profile is used to modify training programs and assist with individual competition strategies. For example, an athlete with a substantial maximal aerobic power (ie, high VO\textsubscript{2} max) would be encouraged to maintain a high intensity of action during a match. On the other hand, an athlete with superior strength and anaerobic capacity might be more selective in the initiation of attacks 28 and be more explosive in the implementation of boxing actions. In this study, we found that athletes presented high VO\textsubscript{2} max. In addition, the elevated HR\textsubscript{max} and% VO\textsubscript{2} max attained during simulated boxing matches indicates that anaerobic complementation is important to this sport. Similar findings have been demonstrated previously for karate and taekwondo athletes. 7,24,29

Reinforcing the importance of aerobic metabolism for performance in boxing, Guidetti et al. examined the relationship between ranking in boxing competition performance and some aerobic physiological parameters in eight middleweight-class elite Italian boxing athletes. A Spearman rho correlation analysis revealed that the VO\textsubscript{2} at the individual anaerobic threshold (46.0 mL·kg\textsuperscript{-1}·min\textsuperscript{-1}±4.2 mL·kg\textsuperscript{-1}·min\textsuperscript{-1}, r = 0.91) and the hand-grip strength (58.2 kg ± 6.9 kg, r = 0.87) were highly correlated (P < 0.01) with boxing competition ranking. VO\textsubscript{2} max (57.5 mL·kg\textsuperscript{-1}·min\textsuperscript{-1}±4.7 mL·kg\textsuperscript{-1}·min\textsuperscript{-1}, r = 0.81) and wrist girth (17.6 cm ± 0.6 cm, r = 0.78) were moderately (P < 0.05) correlated. These data suggest

that two basic factors are related to boxing performance: physical fitness, as indicated by individual anaerobic threshold and maximal oxygen uptake, and upper body muscular strength, as indicated by hand-grip strength (related to anaerobic metabolism).

Despite the development of lightweight, portable metabolic devices to measure physiological responses during an activity, one of the difficulties of working with boxing (and other combat sports) is measuring the $\dot{V}O_2$ during a match. Another reason $\dot{V}O_2$ was not measured in the current study is our intent to maintain the “ecological validity” of simulated matches. The term “ecological validity” in this setting refers specifically to the interaction of boxing athletes with their natural environment and practices. Therefore, we estimated the $\dot{V}O_2$ during the simulated boxing match. We verified that $\dot{V}O_2$ attained during the matches reflected the high intensity of boxing, as mentioned above. Again, these results underscore the importance of a minimum of aerobic fitness for boxing athletes and suggest some guidelines for the intensity of training, in accordance with the literature.

Increases in physiological variables ($\dot{V}O_2$ and HR) were observed over the course of the simulated boxing match and similarly in other intermittent sport activities. In addition, indirect $\dot{V}O_2$ estimation by HR-$\dot{V}O_2$ relationship is commonly considered acceptable for intermittent activities. This indicates that there was a greater energy demand for the completion of high-intensity actions as sparing progressed. We suggest three factors that could be related to the increase in physiological demand during the match. First, athletes may have been under thermal stress due to protective garments. Second, the short rest periods between rounds (1 minute) did not allow sufficient time for physiological variables to decline. A third possibility is that each participant’s competition strategy led to increased demand in each round. It is common for combat-sport athletes to save energy for the last period of the combat, when the most decisive attacks normally occur, resulting in an increase in the metabolic response during the last round.24,30

Finally, of particular interest in this study, was the ability of the athletes to recover their HR between rounds as analyzed through the relationships between aerobic variables ($\dot{V}O_2$, $\dot{V}O_2_{max}$, $\dot{V}O_2_{peak}$, VT1, and VT2) and the decrease in HR. We found no correlations between these variables. There are two explanations for this: First, in martial arts environments, HR overestimations have been attributed to the static nature of upper and lower limb movements or only to upper limb movements (small muscle mass), which seems plausible.33 However, HR overestimations may also be attributed to emotional factors or thermal stress (as mentioned above). Together, these factors can contribute to a failure of HR to show appreciable recovery between work intervals.34 Second, HR recovery following exercise is controlled by complex interactions between neural and hormonal factors.35 In this context, systemic stress metabolite accumulation during postexercise recovery (eg, plasma epinephrine, lactate, H+, and inorganic phosphate) might promote sympathetic activity via chemoreflex control of HR and, consequently, delay HR recovery. Buchheit et al compared the HR recovery response among children, adolescents, and adults, while also taking into account power output and the postexercise blood lactate concentration and acidosis. These authors showed that children experienced significantly faster HR recovery compared with their adolescent and adult counterparts. This apparent difference in HR recovery was associated with lower blood lactate and H+ in children compared with adolescents and adults because children have an immature capacity for anaerobic metabolism. Although the concentration of lactate was not measured in this study, it is likely that our volunteers presented a high concentration of this blood metabolite because, as mentioned earlier, this activity is of high intensity and therefore requires a significant anaerobic contribution.

**Strengths and limitations of this study**

First, our sample contained female and male participants. There are obvious differences in physiological and morphological characteristics between sexes (Table 1 and 2). For instance, women have a lower lung volume, cardiac output, $\dot{V}O_2$, max, and hemoglobin concentration as well as a greater body fat content compared to men. However, there

**Notes:** Data are presented as the means ± standard deviation. Different from Round 1 (P < 0.05); different from Round 2 (P < 0.05). Δ (%) was calculated as percentage of peak HR<sub>152</sub> (HR<sub>152</sub> - HR<sub>60sec</sub>) / HR<sub>152</sub> x 100. Effect size is a measure that describes the magnitude of the difference between two groups.

**Abbreviations:** bpm, beats per minute; HR, heart rate; HR<sub>152</sub>, heart rate measured immediately at the end of the round; HR<sub>60sec</sub>, heart rate measured after 60 seconds of recovery; HR<sub>152</sub> - HR<sub>60sec</sub> (%), percentage of recovery between the end of the round and after 60 seconds of recovery.
is evidence that physiological responses to exercise are not
different between sexes, especially when HR, blood lactate,
and percentage of $\dot{V}O_2$ max are analyzed during exercise.\(^3\)
Therefore, cardiovascular and metabolic strain seems to be
comparable between sexes for the investigated situation in
the present study.

Second, only ten participants were enrolled in the study
due to the difficulty of recruiting elite boxers. Attaining high
participant numbers is an inherent challenge in studies that
involve a specific population, such as elite athletes. Other
studies dealing with combat sports have employed participant
numbers similar to our study or fewer.\(^3,4,24,29\) Therefore, it
is conceivable that the participants enrolled represent the
typical amateur boxer.

Third, the fight was not recorded, so we were not able to
assess movements performed by these boxers, such as high
intensity offensive and defensive techniques, the distance
covered by the athletes, and work/rest ratios. These variables
may interfere with HR responses during a fight.

Notwithstanding these limitations, this study demonstrates
that boxing involves a high demand on the cardiovascular
system and aerobic system, as evidenced by values of HR
corresponding to vigorous and very vigorous exercise. The
same can be said of the estimated $\dot{V}O_2$. Regarding whether
aerobic fitness is an important determinant for the recovery
of HR, this study found no statistically significant correlation
between recovery of HR and $\dot{V}O_2$ max. It appears that in
boxing, undertaking specific training to improve aerobic
capacity seems to be necessary for the rapid recovery of
HR between rounds. In summary, the present investigation
provides baseline physiological data that can be used in the
prescription of individual training programs for boxing
athletes. These data are also important to coaches and can
contribute to competition strategies for individual athletes
and in individual matches. Furthermore, training protocols
should include exercises that train both aerobic and anaerobic
energy pathways, and amateur boxing could be used to
develop aerobic fitness.

Acknowledgments
We are grateful to the directors of the Olympic Center of
Research and Training (Prefeitura Municipal de São
Paulo, Brazil) and Mr Messias Gomes for their technical
assistance. We also thank all the athletes who volunteered
to participate in this study. CABL received a fellowship from
the Coordenação de Aperfeiçoamento de Pessoal de Nível
Superior (CAPES [Coordenação de Aperfeiçoamento de
Pessoal de Nível Superior], Brazil).

This work was supported by the Financiadora de Estudos e
Projetos (FINEP, Brazil).

Author contributions to this work were as follows: CABL and LFP-P: study concept and design, data acquisition, analysis, interpretation, and manuscript preparation; AAA and RLV: data analysis, interpretation, and manuscript preparation; MSA and RJFGF: data acquisition and critical revision of the manuscript; ACS: study concept and design, data analysis, interpretation, and critical revision of the manuscript. CABL and LFP-P contributed equally to this work and may be cited in interchangeable order.

Ethics approval was granted by the Committee of Ethics in Research from UNIFESP (Federal University of São
Paulo).

Disclosure
No commercial party having a direct financial interest in the
results of the research presented in this article has or will
confer a benefit upon the authors or upon any organization
with which the authors are associated. There is no additional
data available from this study. The authors report no conflicts
of interest in this work.
