Background: Targeted liposome-polycation-DNA complex (LPD), mainly conjugated with antibodies using functionalized PEG derivatives, is an effective nanovector for systemic delivery of small interference RNA (siRNA). However, there are few studies reporting the effect of different conjugation linkers on LPD for gene silencing. To clarify the influence of antibody conjugation linkers on LPD, we prepared two different immunoliposomes to deliver siRNA in which DSPE-PEG-COOH and DSPE-PEG-MAL, the commonly used PEG derivative linkers, were used to conjugate anti-EGFR Fab' with the liposome.

Methods: First, 600 µg of anti-EGFR Fab' was conjugated with 28.35 µL of a micelle solution containing DSPE-PEG-MAL or DSPE-PEG-COOH, and then post inserted into the prepared LPD. Various liposome parameters, including particle size, zeta potential, stability, and encapsulation efficiency were evaluated, and the targeting ability and gene silencing activity of TLPD-FPC (DSPE-PEG-COOH conjugated with Fab') was compared with that of TLPD-FPM (DSPE-PEG-MAL conjugated with Fab') in SMMC-7721 hepatocellular carcinoma cells.

Results: There was no significant difference in particle size between the two TLPDs, but the zeta potential was significantly different. Further, although there was no significant difference in siRNA encapsulation efficiency, cell viability, or serum stability between TLPD-FPM and TLPD-FPC, cellular uptake of TLPD-FPM was significantly greater than that of TLPD-FPC in EGFR-overexpressing SMMC-7721 cells. The luciferase gene silencing efficiency of TLPD-FPM was approximately three-fold high than that of TLPD-FPC.

Conclusion: Different conjugation linkers whereby antibodies are conjugated with LPD can affect the physicochemical properties of LPD and antibody conjugation efficiency, thus directly affecting the gene silencing effect of TLPD. Immunoliposomes prepared by DSPE-PEG-MAL conjugation with anti-EGFR Fab' are more effective than TLPD containing DSPE-PEG-COOH in targeting hepatocellular carcinoma cells for siRNA delivery.

Keywords: liposome-polycation-DNA, anti-EGFR Fab', immunoliposomes, small interfering RNA delivery, conjugation technology, hepatocellular carcinoma

Introduction

In the late 1990s, the discovery of RNA interference by Fire et al¹ opened up an entirely new field of "gene" therapy. Since then, RNA interference has been demonstrated by clinical trials as a potential therapy for different kinds of human diseases.³⁻⁵ These small interfering RNA (siRNA), 21–23 nucleotides in length, result in silencing of the corresponding gene by downregulation of the complementary messenger RNA for the selected specific sequence.⁶⁻⁸ However, it is a challenging task to systemically deliver

siRNAs into target cells, because siRNAs themselves are unstable in the bloodstream and cannot penetrate cellular membranes.⁹ To overcome these obstacles, a number of delivery systems have been developed, including lipid-based systems, polymer-based systems, peptide conjugates, and single-chain fragment variable antibody fusion protein systems.^{10–15}

Among the various systems studied, the lipid-based delivery system has received more attention as a promising carrier for siRNA delivery owing to its simplicity of production, relatively low immunogenicity, and absence of oncogenicity.^{16–19} The liposome-polycation-DNA complex (LPD) system, prepared by condensing the siRNA and DNA with protamine into a compact complex followed by coating with cationic liposomes, is an effective lipidic nanovector for systemic siRNA delivery, and was developed in 1996 by Lee and Huang.² To overcome the kinetic and physical barriers to systemic siRNA delivery, it is necessary to develop PEGylated immunoliposomes conjugated with targeting ligands.^{20,21} Huang et al^{22,23} developed an anisamide-targeted LPD system and used it successfully to deliver siRNA to tumor cells overexpressing the sigma receptor. To extend further the application of this LPD system, we adopted the anti-epidermal growth factor receptor (EGFR) Fab' as the targeting ligand for LPD, knowing that it has higher specificity and affinity than the small molecule ligand, and is thus able to provide flexible conjugation sites for crosslinking of nanoparticles. LPD modified with anti-EGFR Fab' has been demonstrated to possess potent gene silencing activity in EGFR overexpressing breast cancer and hepatocellular carcinoma.^{24,25} In our previous study, we investigated the effect of antibody type and amount on the essential physicochemical properties and targeting efficiency of targeted LPD conjugated with anti-EGFR antibody (TLPD), and obtained an optimized siRNA delivery system. However, it remains unclear whether the antibody conjugation linker via which the anti-EGFR Fab' is conjugated to LPD would also affect the physicochemical properties and targeting ability of LPD and further influence the gene delivery effect of LPD. Few studies have demonstrated whether different conjugation linkers would affect the essential physicochemical properties and targeting efficiency of immunoliposomes in siRNA delivery.

Since the procedures for producing highly specific monoclonal antibodies became well established, a number of methods have been reported for coupling antibodies to the surface of stealth liposomes. To obtain specific targeting liposomes with the ability to escape the reticuloendothelial system, functionalized poly(ethylene glycol) PEG derivatives

have been successfully employed in the preparation of immunoliposomes. DSPE-PEG-MAL (1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethylene glycol)-2000] (ammonium salt)) and DSPE-PEG-COOH (distearoyl-N-(3-carboxypropionoyl poly(ethylene glycol) succinyl)phosphatidylethanolamine) have different characteristics and are commonly used as functionalized PEG derivatives to conjugate liposomes with antibodies. For DSPE-PEG-MAL, antibody molecules are thiolated first by 2-iminothiolane (Traut's reagent) to generate a sulfhydryl group and then reacted with maleimide groups on PEG termini. However, antibody molecules thiolated using Traut's reagent can lose substantial amounts of available thiol to recyclize in hours by attacking the amidine carbon. Therefore, once thiolated, the product should be used immediately to avoid significant loss of activity.²⁶ For DSPE-PEG-COOH, antibody molecules are reacted with a carboxyl functional group on PEG termini, so that the antibody does not undergo prior ligand modification, thus reducing the risk of denaturation and loss of its specific activity. Maruyama et al²⁷ used DSPE-PEG-COOH conjugation with a monoclonal immunoglobulin G antibody to prepare the immunoliposome, which had been demonstrated to bind effectively to the designated target site *in vivo*.

Because LPD is a complex colloidal delivery system, physicochemical characteristics, including particle size and surface charge, play an important role in determining the final destination of the complex *in vivo*. Different PEG linkers through which the antibody is conjugated to the liposome may lead to different antibody conjugation efficiency and colloidal properties, which finally can result in different gene silencing effects. Although there are different features and extensive applications in antibody conjugation of the two linkers, there are few studies reporting which immunoliposome prepared by the two functionalized PEG linkers is more efficient in silencing siRNA expression.

To determine which PEG linker is more efficient in delivering siRNA, we prepared two immunoliposomes modified with two functionalized PEG derivatives (DSPE-PEG-COOH or DSPE-PEG-MAL) conjugated with anti-EGFR Fab' via a post-insertion approach. SMMC-7721 hepatocellular carcinoma cells in which EGFR is overexpressed were chosen as the model cell line to determine the specificity of the delivery system. To assess the effect of the two antibody conjugation technologies on siRNA delivery, the essential physicochemical properties and targeting efficiency of the two immunoliposomes were compared *in vitro*.

Materials and methods

Materials

Cholesterol and all lipids were obtained from Avanti Polar Lipids (Alabaster, AL, USA). 1-Ethyl-3-(3-dimethylamino-propyl)carbodiimide (EDC), N-hydroxysuccinimide (NHS), 2-(N-morpholino)ethanesulfonic acid (MES), calf thymus DNA (for hybridization), and protamine sulfate salt (Grade X from salmon) were from Sigma-Aldrich (St Louis, MO, USA). Traut's reagent was from Pierce (Oud Beijerland, The Netherlands). The anti-EGFR Fab' was prepared as we have described previously²⁸ and supplied by the National Engineering Research Center for Antibody Medicine (Shanghai, People's Republic of China).

Anti-luciferase siRNA (antisense, 5'-UCGAAGUACU-CAGCGUAAGTT-3'; sense, 5'-CUUACGCUGAGU-ACUUCGATT-3'), negative control siRNA (NC), anti-RhoA siRNA, and FAM-labeled NC siRNA (FAM-siRNA) were synthesized by GenePharma Co, Ltd (Shanghai, People's Republic of China). Cy5-labeled NC siRNA (Cy5-siRNA) was synthesized by Ribobio Co, Ltd (Guangzhou, People's Republic of China). The siRNAs were delivered in lyophilized form, and upon delivery, were diluted to obtain a 20 μ M solution using RNase-free water provided by GenePharma Co, Ltd.

Cell culture

SMMC-7721 cells (a human hepatocellular carcinoma cell line) were obtained from American Type Culture Collection (ATCC, Manassas, VA, USA) and stably transfected with luciferase gene using a pcDNA3.1 vector. The cells were grown as recommended by ATCC and maintained in Dulbecco's Modified Eagle's Medium supplemented with 10% fetal bovine serum, 25 mM HEPES buffer, 100 U/mL penicillin, and 100 mg/mL streptomycin in a humidified atmosphere of 5% CO₂ at 37°C.

Preparation of liposomes containing siRNA

Naked LPDs were prepared as previously described.²⁵ Briefly, cationic liposomes composed of DOTAP and cholesterol (1:1 molar ratio, 10 mM) were prepared using the thin film hydration method and 0.1% (molar ratio) carboxyfluorescein-PE was added in the lipid film to form fluorescent liposomes. Next, 124 μ L of cationic liposomes, 15 μ L of protamine 2 mg/mL, and 11 μ L of diethylpyrocarbonate water were mixed as solution A, and 90 μ L of siRNA (24 μ g, 20 μ M), 2.4 μ L of calf thymus DNA (24 μ g, 10 mg/mL), and 57.6 μ L of diethylpyrocarbonate water were mixed as solution B. Solutions A and B were then mixed

quickly to form naked LPD. For DSPE-PEG-MAL conjugated with Fab', 600 μ g of thiolated anti-EGFR Fab' and a micelle solution containing DSPE-PEG-MAL (10 mg/mL, 28.35 μ L) were first incubated at 4°C overnight. For DSPE-PEG-COOH conjugated with Fab', 67.5 μ L of NHS 0.25 M and 67.5 μ L of EDC 0.25M were first mixed with 28.4 μ L of micelle solution containing DSPE-PEG-COOH 10 mg/mL, dissolved in MES buffer (10 mM MES/150 mM NaCl, pH 5.5), and kept at room temperature for 15 minutes. The mixture was then neutralized with 1 M NaOH to pH 7.5 and incubated with the desired amount of anti-EGFR Fab' (600 μ g) at 4°C with gentle stirring overnight. The following day, the naked LPD was mixed at 50°C for 10 minutes with the antibody-conjugated micelles to form TLPD-FPM or TLPD-FPC (Figure 1A).

Nontargeted control LPD (NTLPD) was prepared by coupling bovine serum albumin instead of anti-EGFR Fab' to the liposomes using the same method as for TLPD. The following designations are used: TLPD-FPM (TLPD conjugated with anti-EGFR Fab' by the post-insertion approach when the linker PEG derivative was DSPE-PEG-MAL) and TLPD-FPC (TLPD conjugated with anti-EGFR Fab' by the post-insertion approach when the linker PEG derivative was DSPE-PEG-COOH).

Particle size and zeta potential

The mean particle size and zeta potential of the liposomes were determined using the Zetasizer Nano series (Malvern Instruments, Malvern, UK). Prior to measurement, the liposomes were diluted in double-distilled water and measurement was carried out at 25°C. Each sample was measured three times and the mean value was calculated.

Transmission electron microscopy

Transmission electron microscopy was performed on a Hitachi H-600 instrument (Tokyo, Japan) at an acceleration voltage of 75 kV. Briefly, freshly prepared formulations were dropped onto a copper grid coated with a carbon membrane and a short incubation was allowed at room temperature. The grid was then tapped with filter paper to remove the aqueous solution on the surface and air-dried. Negative staining was performed by addition of a drop of 2% phosphotungstic acid to the copper grid with the sample.

siRNA encapsulation efficiency

An Amicon® Ultra-4 centrifugal filter device (100,000 nominal molecular weight limit, Millipore, Bedford, MA, USA) was used to determine the encapsulation efficiency of siRNA by ultrafiltration of the liposomes entrapping FAM-siRNA, as

Figure 1 (A) Procedures involved in developing naked LPD and TLPD. (B) Thiolation of antibodies using Traut's reagent and conjugation of thiolated antibody to maleimide groups on the DSPE-PEG-MAL. (C) Conjugation of DSPE-PEG-COOH with antibody.

Abbreviations: LPD, liposome-polycation-DNA complex; TLPD, targeted liposome-polycation-DNA; DSPE-PEG-MAL, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethylene glycol)-2000] (ammonium salt); DSPE-PEG-COOH, distearoyl-N-(3-carboxypropionyl poly(ethylene glycol) succinyl)phosphatidylethanolamine; EDC, 1-ethyl-3-(3-dimethylamino-propyl)carbodiimide; DOTAP, 1,2-dioleoyl-3-trimethylammoniumpropane; NHS, N-hydroxy succinimide; DNA, deoxyribonucleic acid; DSPE-PEG, distearoyl-N-(monomethoxy poly(ethylene glycol) succinyl)phosphatidylethanolamine; Fab', antigen-binding fragment; SH, hydrosulfide group; NH⁺, imido-group.

described elsewhere.^{24,25} siRNA encapsulation efficiency was estimated from the following equation: $(Q_0 - Q_n)/Q_0 \times 100\%$, where Q_0 and Q_n represent the quantity of siRNA originally added and the quantity of unencapsulated siRNA, respectively.

Gel retardation assay

A gel retardation assay was used to assess the binding affinity of siRNA in liposomes. The liposomes were first solubilized in 5% Triton-X100, then added to independent wells of 2% agarose gel, and finally electrophoresed and visualized with Goldenview™ dye staining. At the same time, untreated liposomes were used as the negative control.

siRNA serum stability

The samples of siRNA solution and the siRNA loaded liposomes were both diluted to the concentration of siRNA about 0.04 µg/µL with diethypyrocarbonate water, and then to 0.02 µg/µL with fetal bovine serum and incubated at 37°C. At different times, after the liposomes were destroyed by 5% Triton-X100, aliquots containing 0.3 µg siRNA of each sample were loaded onto agarose gel for electrophoresis.

In vitro cell viability study

Cell viability was detected using a Cell Counting Kit-8 (CCK-8, Dojindo Laboratories, Kumamoto, Japan) according

to the manufacturer's protocol. Briefly, SMMC-7721 cells were seeded one day prior to the experiment in a 96-well plate at a density of 3×10^4 cells/well in complete Roswell Park Memorial Institute medium containing 10% fetal bovine serum. Following overnight culture, the cells were treated with the liposomes (the final siRNA concentration was 100 nM or 200 nM) in serum containing medium at 37°C. After a 24-hour incubation period, the cells were washed once with phosphate-buffered saline and the medium was exchanged for fresh culture medium. After a total incubation time of 48 hours, 10 µL of CCK-8 solution was added to each well and incubated for 2 hours at 37°C and absorbance was measured using a microplate reader (Bio-Tek, Winooski, VT, USA) at 450 nm/630 nm. Cell viability in each group was calculated as follows: $(A_E - A_B)/(A_U - A_B) \times 100\%$, where A_E , A_U , and A_B represent the absorbance of experimental samples, untreated samples, and blank controls, respectively.

Confocal microscopic study

Cellular uptake experiments were performed to compare the effect of receptor-mediated endocytosis exerted by anti-EGFR Fab'-conjugated immunoliposomes with two different linkers. Briefly, SMMC-7721 cells were seeded on 22 × 22 mm coverslips at a density of 2.5×10^5 /well and treated with 0.1% carboxyfluorescein-PE-labeled liposomes dispersed

in serum containing medium, at 37°C for 2 hours, in which the concentration of Cy5 labeled siRNA was 100 nM. The cells were fixed with 4% paraformaldehyde after washing with phosphate-buffered saline twice and incubated with 4',6-diamidino-2-phenylindole dihydrochloride (DAPI, Sigma, Fluka Chemie, Buchs, Israel) for nuclei staining. Immunofluorescence was then observed using a TCS SP5 confocal microscope (Leica Micro-systems, Exton, PA, USA).

In vitro siRNA transfection study

To study the transfection efficiency of the anti-EGFR Fab'-conjugated immunoliposome in vitro, SMMC-7721 cells (6×10^4 per well) were seeded in 48-well plates overnight. The cells were treated with fluorescently labeled liposomes loaded with siRNA (FAM-siRNA, at a concentration of 250 nM or 500 nM) for 24 hours, trypsinized, and washed by centrifugation (5 minutes, $1,200 \times g$) in ice-cold phosphate-buffered saline supplemented with 1% fetal bovine serum. The resulting cell pellet was resuspended in ice-cold phosphate-buffered saline supplemented with 1% fetal bovine serum. Fluorescence analysis of a minimum of 10,000 events per sample was performed using a FACScanto flow cytometer (Becton Dickinson, San Jose, CA, USA).

In vitro study of siRNA-mediated gene silencing

To compare the in vitro gene silencing effect of TLPD-FPM with that of TLPD-FPC, SMMC-7721 cells with stable luciferase expression were seeded one day prior to the experiment in 48-well plates. The cells were treated with different concentrations of liposomes containing anti-luciferase or NC siRNA at 37°C for 24 hours. The transfection medium was then changed to fresh culture medium. Following a 48-hour incubation period, the cells were washed with phosphate-buffered saline and lysed by incubation in 100 μ L of cell lysis buffer at room temperature for 20 minutes. After mixing 5 μ L of lysate with 25 μ L of substrate from a luciferase assay system kit (Promega, Madison, WI, USA), the luminescence was measured using a 96 microplate luminometer (Glomax™, Promega). The protein concentration in the lysate was determined using a bicinchoninic acid assay (Beyotime Biotechnology, Haimen, People's Republic of China). Luciferase activity was calculated according to the following equation: $(Li_s/C_s)/(Li_N/C_N) \times 100\%$, where Li_s and C_s represent luminescence intensity and the protein concentration of the sample, respectively, and Li_N and C_N represent the luminescence intensity and protein concentration of the untreated control.

In vitro study of RhoA silencing on cell migration

A Boyden chamber assay was employed to evaluate RhoA silencing on migration of SMMC-7721 cells. Briefly, cells (1.25×10^5 cells/well) were seeded overnight in 24-well plates. The cells were then treated with anti-RhoA or NC siRNA-loaded liposomes at a final siRNA concentration of 500 nM and grown for 24 hours. After removal of these complexes, the cells were cultured for an additional 48 hours. Total RNA was extracted from the cells and cDNA was reverse-transcribed from RNA. RhoA silencing was measured by real-time polymerase chain reaction using a 7,500 sequence detection system (Applied Biosystems, Foster City, CA, USA). In addition, SMMC-7721 cells at a density of 1×10^5 were trypsinized and seeded into the upper 8.0 μ m pore size membrane inserts in the tissue culture plates. Culture medium was placed in the bottom wells. Following a 48-hour incubation period, the cells were fixed and stained with 1% crystal violet solution. Cells that migrated through the filter were counted in five random fields, and the mean number was calculated.

Statistical analysis

The statistical significance of the data was evaluated using the Student's *t*-test. A *P*-value ≤ 0.05 was considered to be statistically significant.

Results and discussion

Preparation of PEGylated immunoliposomes

The degree of PEGylation is key for efficient gene delivery using PEGylated LPD nanoparticles. On the one hand, PEGylation can protect LPD against nonspecific uptake by the reticuloendothelial system, thus ensuring circulating LPD nanoparticles have enough time to reach the target tissue via the enhanced permeation and retention effect. On the other hand, PEGylation represents a major barrier for endosomal escape.²⁹ In our previous study, the degree of PEGylation of anti-EGFR-Fab'-conjugated LPD was optimized as 7.5 mol%, which was demonstrated to have targeting ability and gene silencing activity in hepatocellular carcinoma cells.²⁴ In the present study, the prepared formulations of TLPD contained 7.5 mol% surface-grafted PEG-phospholipid conjugated with anti-EGFR Fab' via the post-insertion method. For antibody conjugation, the thiolated anti-EGFR Fab' was conjugated with DSPE-PEG-MAL by forming a thiol-ether bond between the thiol and maleimide groups (Figure 1B).

For conjugation between DSPE-PEG-COOH and anti-EGFR Fab', the coupling reaction was carried out in the presence of EDC and NHS to form an acyl amino ester, which could subsequently react with the primary amine of the ligand to yield an amide bond (Figure 1C).

Characterization of liposomes

Particle size and zeta potential

We prepared different formulations of liposomes composed of DOTAP and cholesterol at a molar ratio of 1:1 using the thin film hydration method with two conjugation techniques. The characteristics of the liposomes are shown in Figure 2. Naked LPD had a size of about 130 nm, but the particle sizes of the four TLPD nanoparticle formulations were similar to each other at about 200 nm, indicating that PEG conjugation

with Fab' was able to increase the size of the liposomes. The size of TLPD with DSPE-PEG-COOH as the conjugation linker seemed larger than that of particles with DSPE-PEG-MAL as the conjugation linker. However, statistical analysis showed that there was no significant difference between the two particle groups. Previous studies^{30,31} have shown that extravasation of PEG-grafted liposomes from the vascular compartment into the tumor interstitium is size-dependent and also dependent on the type of tumor, but mainly limited by the ability to diffuse through the 100–1,200 nm pores in the vessel wall. Thus, a particle size of immunoliposomes at 200 nm is critical for them to pass through the small capillaries and penetrate throughout the tumor.

The surface charge on liposomes plays an important role in determining their final destination. When liposomes

Figure 2 Mean size (A) and zeta potential (B) of LPD, TLPD-FPM, NTLPD-FPM, TLPD-FPC, and NTLPD-FPC. Data are expressed as the mean $\pm$ standard deviation ($n = 3$). **Abbreviations:** LPD, liposome-polycation-DNA; TLPD, targeted liposome-polycation-DNA; TLPD-FPM, targeted LPD when linker PEG was DSPE-PEG-MAL; TLPD-FPC, targeted LPD when linker PEG was DSPE-PEG-COOH; NTLPD-FPM, nontargeted control LPD when linker PEG was DSPE-PEG-MAL; NTLPD-FPC, nontargeted control LPD when linker PEG was DSPE-PEG-COOH; DSPE-PEG-MAL, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethylene glycol)-2000] (ammonium salt); DSPE-PEG-COOH, distearoyl-N-(3-carboxypropionyl poly(ethylene glycol) succinyl)phosphatidylethanolamine; EDC, 1-ethyl-3-(3-dimethylamino-propyl)carbodiimide.

have a strong anionic charge, they are usually absorbed by scavenger cells, resulting in the injected dose being rapidly eliminated from the blood. A strong positive charge can also create some problems. In our prepared LPD system, the mean zeta potential of naked LPD was 49.4 ± 4.1 mV ($n = 4$). This highly positively charged nanoparticle formulation tended to aggregate when incubated with high-salt buffer or serum³² and had a strong charge-charge interaction with cells. When the naked LPD was modified by PEG conjugated with antibody, the zeta potential of the formulations decreased rapidly, indicating that PEG derivatives had inserted into LPD. We found that TLPD-FPM and NTLPD-FPM were similar as no more than 8 mV (Figure 2B), but TLPD-FPC and NTLPD-FPC decreased to about -11 mV, probably due to the negative charge of DSPE-PEG-COOH itself. The difference in zeta potential between the two types of LPD may have an influence on electrostatic interactions with targeted cells.

Transmission electron microscopy

Transmission electron microscopy was used to visualize the particle structure of the different post-inserted functionalized PEG derivatives, TLPD-FPM and TLPD-FPC. Figure 3 shows that there is no difference in shape or size distribution between TLPD-FPM and TLPD-FPC, suggesting that the different post-inserted PEG derivatives conjugated with Fab' have little impact on the structure of the liposomes. Notably, the particles observed by transmission electron microscopy were smaller than those observed by dynamic light scattering (Figure S1). The reason may be that large-sized particles showed significantly greater light

scattering compared with small-sized particles at the same concentration.²⁵

Gel retardation assay

The effect of the different conjugation techniques on the siRNA binding affinity of liposomes was evaluated using a gel retardation assay. Figure 4A shows that encapsulated siRNA was completely retarded in the gel wells when the samples were added directly. However, when Triton-X100 destroyed all liposomes of intact naked LPD, TLPD-FPM, NTLPD-FPM, TLPD-FPC, and NTLPD-FPC, siRNA was released from the liposomes, presenting as bright bands. These results indicate that the siRNA binding affinity remains powerful regardless of different Fab' conjugation technologies, confirming that the siRNA binding affinity would not be affected by these different technologies.

siRNA encapsulation efficiency

Cationic liposomes with their positive charge can absorb negatively charged siRNA to increase encapsulation efficiency.¹⁹ LPD as an effective nanovector for systemic siRNA delivery has high encapsulation efficiency, not only because of the positive charge, but because of the thymus DNA used as a carrier in this formulation to improve core compaction. The different Fab' conjugation technologies used for LPD did not change the particle structure (Figure 3), but the effect on encapsulation efficiency remains unknown. It was found that the siRNA encapsulation efficiency of all liposomes was as high (about 90%) as that of naked LPD (Figure 4B), which is consistent with the result obtained from the gel retardation assay, indicating that there was hardly any impact on siRNA

Figure 3 Transmission electron microscopic images of TLPD-FPM (A) and TLPD-FPC (B). Bar indicates 100 nm.

encapsulation efficiency for TLPD or NTPD using the different Fab' conjugation technologies.

siRNA degradation in serum

In our previous study, we demonstrated that LPD was an effective carrier that could protect siRNA against the influence of external factors. To observe whether different PEG derivatives can block siRNA degradation in serum, all

samples were incubated in an aqueous solution of 50% serum at 37°C, and then agarose gel electrophoresed at designated time points. As shown in Figure 5, after a 6-hour incubation period, naked siRNA was broken down completely (lane 2), while siRNA molecules entrapped inside the PEGylated liposomes remained relatively intact even after 48 hours, irrespective of the method of preparation. These results suggest that both conjugation technologies efficiently protected siRNA against serum, which is consistent with the finding of Kim et al that PEGylated liposomes increased the stability of siRNA against RNase.³³ LPD with the two different PEG derivatives also had the same effect of prolonging the residence time of liposomes in serum by providing a steric barrier.

Cell viability

Prior to the siRNA transfection experiment, we investigated the cytotoxicity of TLPD-FPM/FPC and NTPD-FPM/FPC in SMMC-7721 cells. As shown in Figure 6, there was no significant decrease in viability of TLPD-FPM/FPC-treated cells or NTPD-FPM/FPC-treated cells after 24 hours of incubation as compared with that in untreated cells, indicating that all the liposome formulations had good biocompatibility with SMMC-7721 cells at concentrations of 100 nM or 200 nM siRNA, and the cytotoxicity of (N)TLPD-FPM was similar to that of (N)TLPD-FPC. Therefore, we can conclude that there is no significant difference in cytotoxicity to SMMC-7721 cells between the two technologies for conjugation of Fabs', and the prepared TLPD system can serve as a secure gene carrier to cells.

Figure 5 siRNA serum stability. Lane 1, intact siRNA; lane 2, siRNA; lane 3, naked LPD; lane 4, TLPD-FPM; lane 5, NTPD-FPM; lane 6, TLPD-FPC; and lane 7, NTPD-FPC. Samples of siRNA solution or liposomes incubated with 50% fetal bovine serum. After the liposomes were destroyed by 5% Triton-X100, these samples containing 0.3 µg siRNA were applied to agarose gel electrophoresis.

Figure 6 Cell viability of SMMC-7721 cells transfected with NTLPD-FPM, TLPD-FPM, NTLPD-FPC, or TLPD-FPC at an siRNA concentration of 100 nM or 200 nM. The data are shown as the mean $\pm$ standard deviation ($n = 3$).

Abbreviations: TLPD-FPM, targeted LPD when linker PEG was DSPE-PEG-MAL; TLPD-FPC, targeted LPD when linker PEG was DSPE-PEG-COOH; NTLPD-FPM, nontargeted control LPD when linker PEG was DSPE-PEG-MAL; NTLPD-FPC, nontargeted control LPD when linker PEG was DSPE-PEG-COOH; DSPE-PEG-MAL, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethylene glycol)-2000] (ammonium salt); DSPE-PEG-COOH, distearoyl-N-(3-carboxypropionyl poly(ethylene glycol) succinyl)phosphatidylethanolamine; NEG, negative.

In vitro cellular uptake of liposome/siRNA complexes

Cellular internalization of siRNA-encapsulated nanoparticles was evaluated by confocal microscopy after culture of nanoparticles with SMMC-7721 cells. As shown in Figure 7, the

uptake of green fluorescently labeled carboxyfluorescein-PE and red fluorescently labeled siRNA was much greater in cells treated with TLPD-FPM than that in TLPD-FPC. Further, for both liposomes containing different conjugation linkers, the fluorescence signal in the cells treated with nontargeted liposomes (Figure 7B and D) was much weaker than that of cells treated with LPD-PEG-targeted liposomes (Figure 7C and E). Taken together, these data indicate that the targeted TLPD-FPM liposome was superior to the targeted TLPD-FPC liposome in efficient delivery of siRNA to tumor cells and that intracellular delivery was ligand-dependent. The results are in good agreement with the transfection efficiency data shown in Figure 8.

In vitro transfection of liposome/siRNA complexes

To investigate the transfection efficiency of the liposomes, SMMC-7721 cells with high EGFR expression were treated with TLPD at a concentration of 250 nM or 500 nM FAM-siRNA for 24 hours. As shown in Figure 8, TLPD-FPM significantly increased the transfection efficiency of SMMC-7721 cells compared with NTLPD-FPM. The transfection efficiency of TLPD-FPC was also higher than that of NTLPD-FPC in 250 nM or 500 nM siRNA, indicating that both immunoliposomes possess targetability. Compared with TLPD-FPC, TLPD-FPM showed higher transfection efficiency of about 1.88-fold and 3.46-fold in 250 nM and

Figure 7 Internalization of the nanoparticles was evaluated by confocal microscopy. SMMC-7721 cells were treated with different formulations of liposomes as follows: (A) row, untreated; (B) row, NTLPD-FPM; (C) row, TLPD-FPM; (D) row, NTLPD-FPC; (E) row, TLPD-FPC. Scale bar 75 μ m.

Abbreviations: LPD, liposome-polycation-DNA; TLPD, targeted liposome-polycation-DNA; TLPD-FPM, targeted LPD when linker PEG was DSPE-PEG-MAL; TLPD-FPC, targeted LPD when linker PEG was DSPE-PEG-COOH; NTLPD-FPM, nontargeted control LPD when linker PEG was DSPE-PEG-MAL; NTLPD-FPC, nontargeted control LPD when linker PEG was DSPE-PEG-COOH; DSPE-PEG-MAL, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethylene glycol)-2000] (ammonium salt); DSPE-PEG-COOH, distearoyl-N-(3-carboxypropionyl poly(ethylene glycol) succinyl)phosphatidylethanolamine; CFPE, carboxyfluorescein-PE; DAPI, 4',6-diamidino-2-phenylindole dihydrochloride.

Figure 8 Cellular uptake of SMMC-7721 cells in vitro. After treatment of the cells at a FAM-siRNA concentration of 250 nM or 500 nM for 24 hours, mean fluorescence intensity was analyzed by flow cytometry. The data are shown as the mean $\pm$ standard deviation ($n = 3$).

Abbreviations: TLPD-FPM, targeted LPD when linker PEG was DSPE-PEG-MAL; TLPD-FPC, targeted LPD when linker PEG was DSPE-PEG-COOH; NTLPD-FPM, nontargeted control LPD when linker PEG was DSPE-PEG-MAL; NTLPD-FPC, nontargeted control LPD when linker PEG was DSPE-PEG-COOH; DSPE-PEG-MAL, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethyleneglycol)-2000] (ammonium salt); DSPE-PEG-COOH, distearoyl-N-(3-carboxypropionyl poly(ethylene glycol) succinyl)phosphatidylethanolamine.

500 nM siRNA, respectively, that could be attributed to their charges, ie, TLPD-FPM or NTLPD-FPM with a positive charge and TLPD-FPC or NTLPD-FPC with a negative charge. These findings are consistent with the results reported by Morille et al¹⁶ that nonviral vectors with a positive charge could bind to a negatively charged cell membrane through electrostatic interactions, leading to higher transfection efficiency than vectors with a negative charge.

In vitro gene silencing

In vitro gene silencing was studied using SMMC-7721 cells stably transduced with the firefly luciferase gene. As shown in Figure 9, the silencing effect in cells treated with targeted liposomes was much higher than that in cells treated with nontargeted liposomes, indicating that Fab' conjugation to liposomes exerted its targeting effect through receptor-mediated endocytosis. In addition, more than 50% silencing was achieved in targeted liposomes containing DSPE-PEG-MAL at a 250 nM siRNA concentration, which was higher than that of targeted liposomes containing DSPE-PEG-COOH. When the siRNA concentration was increased to 500 nM, the silencing efficiency for TLPD-FPM reached about 80% versus 32% for TLPD-FPC. On the basis of these data, we can conclude that gene silencing activity is highly correlated with intracellular siRNA uptake (Figure 7) and transfection efficiency (Figure 8). As TLPD-FPM showed higher intracellular siRNA uptake and more efficient in gene transfection than TLPD-FPC, TLPD-FPM is more efficiently in silencing reporter gene in hepatocellular carcinoma cells.

Figure 9 In vitro gene silencing. The percent luciferase activity of SMMC-7721 after transfection with (A) TLPD-FPM, NTLPD-FPM and (B) TLPD-FPC, NTLPD-FPC at a concentration of 250 nM or 500 nM siRNA. The data are shown as the mean $\pm$ standard deviation ($n = 3$). * $P < 0.05$.

Abbreviations: TLPD-FPM, targeted LPD when linker PEG was DSPE-PEG-MAL; TLPD-FPC, targeted LPD when linker PEG was DSPE-PEG-COOH; NTLPD-FPM, nontargeted control LPD when linker PEG was DSPE-PEG-MAL; NTLPD-FPC, nontargeted control LPD when linker PEG was DSPE-PEG-COOH; LUC, luciferase; NC, negative control siRNA; DSPE-PEG-MAL, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethylene glycol)-2000] (ammonium salt); DSPE-PEG-COOH, distearoyl-N-(3-carboxypropionyl poly(ethylene glycol) succinyl)phosphatidylethanolamine.

Cell migration after RhoA silencing

As a small Rho GTPase, RhoA has been shown to play a key role in regulation of tumor growth, migration, and response to therapy.³⁴ When the cell surface receptor is simulated, RhoA becomes activated and regulates tumor growth, migration, and gene expression through Rho kinases and ROCK.³⁵ RhoA has been used as a therapeutic target to demonstrate the potential of TLPD-FPM and TLPD-FPC in cancer gene therapy. In contrast with untreated cells, transfection of SMMC-7721 cells with TLPD-FPM and TLPD-FPC containing anti-RhoA siRNA reduced RhoA messenger RNA expression by 70% and 30%, respectively (Figure 10C) and appeared to suppress cell migration compared with NTLPD-FPM and NTLPD-FPC containing anti-RhoA siRNA (Figure 10A and B). As expected, targeted or nontargeted LPD of the two different conjugation technologies entrapping NC siRNA had no RhoA gene silencing activity and could not inhibit SMMC-

Figure 10 RhoA silencing of SMMC-7721 cell migration. The cells were treated with anti-RhoA or NC siRNA encapsulated in liposomes at a final siRNA concentration of 500 nM. **(A)** After 48 hours of transfection, cell migration induced by RhoA was assessed. Original magnification $\times 200$. **(B)** The number of cells per field was calculated from five random fields. **(C)** After 72 hours of transfection, total RNA was extracted from the cells and RhoA expression was demonstrated by real-time polymerase chain reaction. The data are shown as the mean $\pm$ standard deviation ($n = 3$).

Abbreviations: TLPD-FPM, targeted LPD when linker PEG was DSPE-PEG-MAL; TLPD-FPC, targeted LPD when linker PEG was DSPE-PEG-COOH; NTPD-FPM, nontargeted control LPD when linker PEG was DSPE-PEG-MAL; NTPD-FPC, nontargeted control LPD when linker PEG was DSPE-PEG-COOH; DSPE-PEG-MAL, 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[maleimide(polyethylene glycol)-2000] (ammonium salt); DSPE-PEG-COOH, distearoyl-N-(3-carboxypropionyl poly(ethylene glycol) succinyl)phosphatidylethanolamine; NC, negative control siRNA; NEG, negative.

7721 cell migration. In summary, anti-RhoA siRNA formulated in targeted liposomes could effectively downregulate RhoA messenger RNA expression and reduce cell migration, and the effect of targeted TLPD-FPM liposome was much higher than that of the targeted TLPD-FPC liposome.

Conclusion

In the present study, we prepared different formulations of liposomes with two Fab' conjugation technologies using the post-insertion method and made a series of comparisons between them using a variety of analytical techniques in vitro. It was found that liposomes prepared by the two conjugation technologies possessed high siRNA encapsulation efficiency,

superior serum stability, and little immunotoxicity, and both could be used as siRNA carriers. In addition, targeted liposomes showed a better effect than untargeted liposomes in transfection efficiency and gene silencing. However, compared with TLPD-FPC, TLPD-FPM showed significantly enhanced EGFR targeting efficiency and achieved superior gene silencing activity in vitro. These findings suggest that when the targeting LPD is modified by anti-EGFR Fab' conjugation with DSPE-PEG-MAL or DSPE-PEG-COOH, the former would have significant superiority in siRNA delivery in comparison with the latter. The data obtained from this study may provide new information about selection of linkers in preparing targeted drug carriers.
