Background: MET is involved in the progression of several types of human cancers, while phospho-BAD(Ser-136) is a key molecule in apoptosis and might be regulated by MET. The aim of this study was to investigate the correlation between altered expression of MET and phospho-BAD in non-small cell lung cancer (NSCLC) and their association with clinicopathologic parameters and overall survival.

Methods: MET and phospho-BAD(Ser-136) proteins were evaluated by immunohistochemical analysis in 183 paraffin-embedded specimens and were also assessed by Western blotting analysis in 12 frozen tumor tissue samples, which were representative examples of immunohistochemical staining.

Results: Positive expression of MET and phospho-BAD(Ser-136) occurred in 67.2% and 49.2% of the 183 cases of NSCLC, respectively. However, neither MET expression nor phospho-BAD(Ser-136) expression was associated with any clinicopathologic parameter. A significant correlation was found between MET and phospho-BAD(Ser-136) expression levels evaluated by immunohistochemistry ($r = 0.268$, $P < 0.001$). Overexpression of MET was significantly associated with shortened overall survival in univariate analysis ($P < 0.001$). Moreover, patients with a MET+/phospho-BAD(Ser-136)+ phenotype had a poorer prognosis than others ($P < 0.001$). Multivariate Cox proportional hazard analysis confirmed that MET expression is a prognostic factor for NSCLC.

Conclusion: MET expression might be correlated with phospho-BAD(Ser-136) expression, and may be an adverse predictor for NSCLC. Activation of the MET/phospho-BAD(Ser-136) signaling pathway might play a role in the development and progression of NSCLC.

Keywords: MET, phospho-BAD, prognosis, non-small cell lung cancer

Introduction

Lung cancer is the leading cause of cancer-related death throughout the world, while 80%–85% of primary lung cancer cases are specifically non-small cell lung cancer (NSCLC).¹ The prognosis of NSCLC cases is usually poor because of late diagnosis and therapeutic limitations. Therefore, exploration of new molecular markers involved in progression of NSCLC can facilitate effective targeted treatment and prognostic assessment. Based on advancement of the knowledge about the molecular mechanisms of NSCLC, much interest has focused recently on an aberrant MET signaling pathway in NSCLC.

MET, which is encoded by the $MET$ gene, is the receptor with the highest affinity for hepatocyte growth factor/scatter factor. Hepatocyte growth factor/scatter factor binds to the MET receptor and results in autophosphorylation of several tyrosine...
residues within the intracellular region, leading to activation of downstream signaling pathways, such as phosphoinositide-3-kinase (PI3K), Ras-Rac/Rho, Ras mitogen-activated protein kinase, and phospholipase C-γ. Thus, the activated hepatocyte growth factor/MET pathway promotes tumor growth, angiogenesis, and metastasis in several types of human cancers, including NSCLC, making it a promising research target for potential anticancer treatment.

MET abnormalities occur frequently in NSCLC, including protein overexpression, gene mutation, and gene amplification. Although several clinical studies have revealed that MET protein is expressed in approximately 70% of adenocarcinoma and 40% of squamous cell carcinoma in lung cancer cases and overexpression of MET is associated with a poor prognosis in NSCLC patients, the clinicopathologic features and prognostic value of MET overexpression remains controversial.

One of the tumorigenic mechanisms responsible for development of NSCLC is evasion of apoptosis. Defects in regulation of apoptosis lead to tumorigenesis and resistance to chemotherapy in various cancer cells. Alterations in proapoptotic and antiapoptotic pathways are common in cancer cells, and regulation of apoptosis is a complicated process that involves a myriad of proteins. In particular, BAD, one of the death-promoting proteins in the Bcl-2 gene family, exerts its death-promoting effect by heterodimerizing with BCL-XL and BCL-2 death antagonists in the mitochondria, and is tightly regulated by survival factors. Dephosphorylation activates BAD protein to initiate apoptosis, while phosphorylation of several serine residues (Ser-112 and Ser-136) will inactivate BAD to promote cell survival. Although phosphorylation of BAD has been shown to contribute to tumorigenesis and drug resistance, the clinical relevance and prognostic value of phospho-BAD protein expression in NSCLC remains unclear. Furthermore, studies have recently presented evidence that AKT, a serine/threonine protein kinase downstream of PI3K, can bind to and phosphorylate BAD at Ser-136 residues in vitro. Thus, activated hepatocyte growth factor/MET signaling may be linked to phosphorylation of BAD at the Ser-136 residual through the PI3K-AKT pathway and play a key role in regulation of cell survival in NSCLC. However, a combined analysis of MET and phospho-BAD abnormalities in NSCLC has never been reported, and this new insight of combining biomarkers might improve the clinical outcome of NSCLC.

In this study, we detected the expression of MET and phospho-BAD(Ser-136) using immunohistochemistry and Western blotting, and explored whether the expression level of MET correlated with phospho-BAD(Ser-136) in these patients. We also investigated their clinicopathologic and prognostic significance in NSCLC.

Patients and methods
Study population
One hundred and eighty-three NSCLC patients who underwent tumor resection at the First Affiliated Hospital of Xi’an Jiaotong University from 2003 to 2010 were enrolled in the study. The patients included 141 males and 42 females aged 44–71 (mean 56.2) years. None of these patients received neoadjuvant chemotherapy before surgery. All patients were followed closely until June 30, 2012, and the mean duration of follow-up was 39.2 ± 12.6 months. Tumor histologic classification and differentiation were done according to the 1999 histologic classification standards of lung cancer published by the World Health Organization. TNM staging was carried out according to the 2004 guidelines of the National Comprehensive Cancer Network for NSCLC. Clinical and pathologic features of the patients enrolled in the study are shown in Table 1. The research was approved by the institutional ethics committee of First Affiliated Hospital of Medical College of Xi’an Jiaotong University. Written informed consent was obtained from each patient.

Immunohistochemistry
First, formalin-fixed and paraffin-embedded tissue sections (4 µm) underwent deparaffinization and hydration. Antigen retrieval was done in buffer (1 mmol/L EDTA/phosphate-buffered saline, pH 9.0) at 98°C for 30 minutes in a water bath. Endogenous peroxide blocking was performed with 3% hydrogen peroxide for 10 minutes. Next, the slides were incubated with rabbit anti-MET antibody (1:200; Santa Cruz Biotechnology Inc, CA, USA) and rabbit antiphospho-BAD(Ser-136) antibody (1:200; Abcam, Cambridge, MA, USA) overnight at 4°C. The stained sections were exposed to a 3,3-diaminobenzidine kit (Zhongshan Biotechnology Inc, Beijing, People’s Republic of China) and finally counterstained with Mayer’s hematoxylin. An irrelevant rabbit antiserum instead of primary antibodies served as the negative control.

Immunohistochemical analysis
The results of staining were evaluated by two independent pathologists who were blinded to the clinical data. Immunohistochemical scoring was based on both the percentage of positive cells and the intensity of staining on five randomly visual fields under the optical microscope. The intensity of staining...

Abbreviations: pBAD<sub>S136</sub>, phospho-BAD(Ser-136); AC, adenocarcinoma; SCC, squamous cell carcinoma; TNM, tumor-node-metastasis.

was scored as: 0, without stain; 1, straw yellow; 2, brown; and 3, dark brown. According to the percentage of tumor cells stained positive, extent of staining was scored as: 0, 0%; 1, 1%–25%; 2, 26%–50%; 3, 51%–75%; or 4, 76%–100%. The final score was the sum of the two scores. Tumor tissues with a final score ≤3 were considered as negative, while those with a final score >3 were considered as positive.

Western blot analysis

An immunoblot assay was done on 12 cases that were assessed by immunohistochemistry and considered to be representative staining examples of MET and phospho-BAD(Ser-136) expression. Total protein was extracted from the fresh frozen tissues using a whole protein extraction kit (KeyGEN, Nanjing, People’s Republic of China) according to the manufacturer’s instructions. Concentration of protein were determined by using the BCA Protein Assay Reagent (Thermo Scientific, Rockford, IL, USA). Equal amounts of total protein from different samples were electrophoresed on a 10% sodium dodecyl sulfate-polyacrylamide gel and transferred to nitrocellulose membrane using standard protocols. Rabbit anti-MET (1:200; Santa Cruz Biotechnology Inc), rabbit antiphospho-BAD(Ser-136) (1:200; Abcam) and rabbit anti-glyceraldehyde 3-phosphate dehydrogenase (GAPDH, 1:3000; Proteinotech Group, Chicago, IL, USA) antibodies and secondary antibody (1:5000; Cell Signaling Technology, Beverly, MA, USA) were used to detect MET, phospho-BAD(Ser-136), and GAPDH proteins, respectively. Proteins were detected by enhanced chemiluminescence (Thermo Scientific).

Statistical analysis

Statistical Package for the Social Sciences version 17.0 software (SPSS Inc, Chicago, IL, USA) was used for the statistical analysis. The association between clinical characteristics and MET and phospho-BAD(Ser-136) expression status was determined using the Chi-squared ($\chi^2$) test. Spearman’s rank correlation analysis was used to analyze the association between MET and phospho-BAD(Ser-136) expression levels. Overall survival curves were calculated using the Kaplan–Meier method and compared by log-rank test. Multivariate analysis
was performed using a Cox proportional hazards regression model analysis. A value of $P < 0.05$ was considered to be statistically significant.

**Results**

Expression of MET and phospho-BAD(Ser-136) in NSCLC by immunohistochemistry and their association with clinicopathologic variables

In this study, the aberrant expression of MET and phospho-BAD(Ser-136) in NSCLC tissue specimens was first evaluated by immunohistochemical analysis. MET protein was primarily localized in the cytoplasm or on the cell membrane of tumor cells, while phospho-BAD(Ser-136) protein was found predominantly in the cytoplasm (Figures 1 and 2). Immunohistochemical staining analysis showed that MET was expressed in 67.2% (123/183) of these NSCLC cases, including 60 adenocarcinomas and 63 squamous cell carcinomas. Phospho-BAD(Ser-136) was expressed in 49.2% (90/183) of these NSCLC cases, including 42 adenocarcinomas and 48 squamous cell carcinomas. However, neither MET nor phospho-BAD(Ser-136) protein was associated with any clinicopathologic characteristics, including sex, age, smoking history, histology, differentiation, T-status, lymph node metastasis, or TNM stage. Detailed results are shown in Table 1.

Association of MET expression level with phospho-BAD(Ser-136) expression in NSCLC by immunohistochemistry and Western blotting

We next investigated the association between MET expression and phospho-BAD(Ser-136) expression in NSCLC by immunohistochemistry, and found there was
a significant association between MET and phospho-
BAD(Ser-136) expression levels (Table 2, Spearman’s
r = 0.268, P < 0.001). Of the 123 tumor tissues with MET-
positive expression, 72 cases (72/123, 58.5%) also displayed
phospho-BAD(Ser-136)-positive expression. According to
the expression status of MET and phospho-BAD(Ser-136),
all NSCLC patients were classified into two groups, ie,
MET+/phospho-BAD(Ser-136)+ (39.3%, 72/183) and others
(60.7%, 111/183). The correlation between the MET+/ phos-
pho-BAD(Ser-136)+ phenotype and clinicopathologic
variables was also analyzed, as shown in Table 1.

To confirm that MET expression was significantly associ-
ated with phospho-BAD(Ser-136) expression, as determined by
immunohistochemistry, protein from frozen tissues of 12 rep-
resentative examples of MET and phospho-BAD(Ser-136)
staining was extracted. Western blotting analysis showed that
high levels of phospho-BAD(Ser-136) were observed only
in the samples with high expression of MET by immuno-
histochemistry, while phospho-BAD(Ser-136) was corres-
dpondingly downregulated in all the samples with low expression
of MET by immunohistochemistry (Figures 1 and 2).

Survival analysis
The correlations between MET and phospho-BAD(Ser-136)
expression level and prognosis in NSCLC patients were ana-
yzed by the Kaplan–Meier method. As shown in Figure 3 and
Table 3, patients with MET-positive expression had a poor pro-
gnosis in NSCLC (P < 0.001; Figure 3A). The median survival
time for MET-positive and MET-negative expression was 38.9
and 60.3 months, respectively. However, expression of phospho-
BAD(Ser-136) was not significantly associated with overall
survival (P = 0.310; Figure 3B). When considering overall sur-

vival and combined status of MET and phospho-BAD(Ser-136)
expression, we found that the MET+/phospho-BAD(Ser-136)+
phenotype was associated with shorter overall survival than the
others (P < 0.001; Figure 3C).

Next, to test whether MET expression was an indepen-
dent prognostic factor in NSCLC patients, we performed a
multivariate survival analysis. Although in univariate analysis,
T-status (P = 0.031), TNM stage (P = 0.001), and MET expres-
sion (P < 0.001), as well as combined expression status of
MET+/phospho-BAD(Ser-136)+ (P < 0.001) were associated
with overall survival, in multivariate analysis, only expres-
sion of MET protein (hazard ratio 4.321, 95% confidence interval
2.508–7.446, P = 0.001), and TNM stage (hazard ratio 2.276,
95% confidence interval 1.305–3.967, P < 0.004) were inde-
pendent prognostic factors in our NSCLC patients. Detailed
data are shown in Tables 3 and 4.

Discussion
In this study, we analyzed the expression of MET and
phospho-BAD(Ser-136) in NSCLC for the first time. MET and
phospho-BAD(Ser-136) proteins were expressed in
67.2% and 49.2% of the study population of NSCLC patients,
respectively, and there was a significant association between
MET and phospho-BAD(Ser-136) expression levels on
both immunohistochemistry and Western blotting. MET
overexpression was associated with poor survival and was
an independent indicator of the prognosis, whereas expres-
sion of phospho-BAD(Ser-136) was not associated with
overall survival.

MET, a high-affinity receptor for hepatocyte growth
factor, is usually considered as an oncogene.18 Hepatocyte
growth factor binds to MET receptor and undergoes phos-
phorylation on intracellular tyrosine residues, leading to
activation of some downstream signaling events. The hepa-
tocyte growth factor/MET pathway has multiple biological
functions, including cell proliferation, motility, angiogen-
esis, and morphogenesis. Although many human cancers
show overexpression of MET, the role of MET overexpres-
sion in the development and progression of NSCLC is not
fully understood. In NSCLC, MET protein is reported to be
overexpressed in tumor tissues relative to adjacent tissues,
and expression rates range between 24.0% and 81.0%.19–22 In
the current study, MET expression positivity was observed in
67.2% (123/183) of resected NSCLC tissues, within
the range of expression rates previously reported, but was
not associated with any clinicopathologic characteristics,
including sex, age, smoking history, histology, differentia-
tion, T-status, lymph node metastasis, or TNM stage. Some
clinical studies have shown that MET expression occurs
more commonly in adenocarcinoma of the lung than in
squamous cell carcinoma.7,19,22 However, consistent with our
study, Masuya et al detected MET protein in 188 NSCLC
patients by immunohistochemistry and also failed to show
any association between positivity of MET expression and
histology.20
Although some studies have confirmed that overexpression of MET is associated with poor survival, the prognostic value of MET expression in NSCLC is debatable. The study reported by Masuya et al showed shortened overall survival in cases with MET-positive expression. Similarly, Ichimura et al analyzed MET expression in 104 NSCLCs using immunohistochemistry and demonstrated a tendency for worse survival in patients with MET-positive expression. Consistent with these data, our study showed that MET-positive expression was associated with poor overall survival in patients with NSCLC. Further, multivariate analysis revealed MET-positive expression to be an adverse prognostic factor that did not correlate with any clinicopathologic characteristics, but the clinical sequence by which MET overexpression leads to poor prognosis remains unclear. Recently, MET overexpression has been reported to contribute to development of acquired chemoresistance and radioresistance via multiple downstream pathways in several types of cancer cells. Thus, MET might be involved in chemoresistance or radioresistance in NSCLC and linked to a poor prognosis. In contrast, Tsuta et al and Dziadziuszko et al reported that expression of MET protein was not associated with survival. The discrepancy may be due to different

BAD is a distant member of the BCL-2 family (critical regulators of cell death in mammalian cells). The function of this proapoptotic molecule is regulated by phosphorylation of two sites, Ser-112 and Ser-136, which is mediated by the serine/threonine protein kinase Akt-1/PKB, downstream of PI3K.\textsuperscript{30} Phosphorylation at either site results in loss of the ability of BAD to heterodimerize with the survival proteins, BCL-XL or BCL-2. Further research has shown that BAD abnormalities contribute to tumorigenesis and resistance to chemotherapy in some malignancies. Ranger et al showed that BAD-deficient mice are prone to develop leukemia/lymphoma.\textsuperscript{12} Gilmore et al found that a primary culture of BAD-/mammary cancer cells was no longer sensitive to gefitinib-induced apoptosis.\textsuperscript{11} Huang et al reported that the BAD expression level decreased significantly in NSCLC, and loss of BAD independently predicted a poor prognosis, especially in smokers.\textsuperscript{29} BAD was also observed to be a prognostic variable for stage II and III colon cancer and breast cancer patients.\textsuperscript{30,31} However, few reported studies have assessed the clinical relevance and prognostic value of phospho-BAD(Ser-136) expression.

The present study found that phospho-BAD(Ser-136) expression was not associated with any clinicopathologic characteristics. Interestingly, our study found that phospho-BAD(Ser-136) expression was significantly associated with MET expression by immunohistochemistry. Moreover, Western blotting in 12 representative NSCLC tissues confirmed increased phospho-BAD(Ser-136) detection only in cases with a high level of MET expression, while phospho-BAD(Ser-136) was correspondingly downregulated in all cases with a low level of MET expression. These data indicate that MET overexpression could upregulate expression of phospho-BAD(Ser-136), although the underlying molecular mechanism remains to be clarified. MET-associated downstream pathways, such as PI3K/AKT, may be responsible.

Although the median survival time for patients with positive phospho-BAD(Ser-136) expression (43 months) was shorter than for patients with negative phospho-BAD(Ser-136) expression (49 months), there was no significant association between the expression level of phospho-BAD(Ser-136) and overall survival. Similarly, Cartron et al detected phospho-BAD(Ser-136) in glioblastoma multiforme tumors using Western blotting and enzyme-linked immunosorbent assay and found no association between the expression level of phospho-BAD(Ser-136) and overall survival.\textsuperscript{32} A possible reason for this may be the presence of many other factors affecting apoptosis in NSCLC.
The present study shows that the expression level of MET is significantly correlated with that of phospho-BAD(Ser-136) and is a negative prognostic factor in multivariate analysis. We investigated the correlation between the combined status of MET and phospho-BAD(Ser-136) expression and overall survival and found that patients with the MET+/phospho-BAD(Ser-136)+ phenotype had poorer overall survival than others at the univariate level. However, this was not an independent prognostic factor in multivariate analysis. This may be because a number of signaling pathways are activated by MET in the progression of NSCLC, except for the MET/phospho-BAD(Ser-136) pathway. Therefore, the current data indicate that MET/phospho-BAD(Ser-136) pathway might play a role in the progression of NSCLC, but not necessarily a dominant one. Further research using a larger sample size is warranted to confirm our data.

Overall, the current study suggests that there is a significant positive correlation between expression of MET and that of phospho-BAD(Ser-136). MET overexpression was shown to be an adverse prognostic marker for patients with NSCLC. Therefore, an activated MET/phospho-BAD(Ser-136) pathway might play a role in the development and progression of NSCLC.
