Abstract: Non-small cell lung cancer (NSCLC) unfortunately carries a very poor prognosis. Patients usually do not become symptomatic, and therefore do not seek treatment, until the cancer is advanced and it is too late to employ curative treatment options. New therapeutic options are urgently needed for NSCLC, because even current targeted therapies cure very few patients. Active immunotherapy is an option that is gaining more attention. A delicate and complex interplay exists between the tumor and the immune system. Solid tumors utilize a variety of mechanisms to evade immune detection. However, if the immune system can be stimulated to recognize the tumor as foreign, tumor cells can be specifically eliminated with little systemic toxicity. A number of vaccines designed to boost immunity against NSCLC are currently undergoing investigation in phase III clinical trials. Belagenpumatucel-L, an allogeneic cell vaccine that decreases transforming growth factor (TGF-β) in the tumor microenvironment, releases the immune suppression caused by the tumor and it has shown efficacy in a wide array of patients with advanced NSCLC. Melanoma-associated antigen A3 (MAGE-A3), an antigen-based vaccine, has shown promising results in MAGE-A3⁺ NSCLC patients who have undergone complete surgical resection. L-BLP25 and TG4010 are both antigenic vaccines that target the Mucin-1 protein (MUC-1), a proto-oncogene that is commonly mutated in solid tumors. CIMA Vax is a recombinant human epidermal growth factor (EGF) vaccine that induces anti-EGF antibody production and prevents EGF from binding to its receptor. These vaccines may significantly improve survival and quality of life for patients with an otherwise dismal NSCLC prognosis. This review is intended to give an overview of the current data and the most promising studies of active immunotherapy for NSCLC.

Keywords: immunotherapy, non-small cell lung cancer, Belagenpumatucel-L, melanoma-associated antigen A3 (MAGE-A3), L-BLP25, TG4010, CIMA Vax

Introduction

Lung cancer is the leading cause of cancer mortality in the US and worldwide, accounting for over one million deaths annually. Approximately 85% of newly diagnosed lung cancers are categorized as non-small cell lung cancers (NSCLC).¹ NSCLC includes squamous cell carcinoma, adenocarcinoma, and large cell carcinoma. Unlike other common types of solid tumors, such as breast cancer and colon cancer, there are no screening modalities for early detection of lung cancer in the general population.²³ As a result, many of these patients have locally advanced or metastatic disease by the time they become symptomatic and present for care. Patients with stage IIIb or IV NSCLC are deemed to have unresectable tumors and while they may benefit from palliative chemotherapy, radiation, or both, a cure is unlikely. Even if the NSCLC
can be completely resected, the 5-year mortality is 40% in stage I disease, 66% in stage II disease, and 75% in stage IIIa loco-regional disease. Micrometastases are commonly left behind after surgical resection, resulting in eventual relapse. As such, a diagnosis of NSCLC carries a poor prognosis under all circumstances.

Systemic chemotherapy for NSCLC has reached a plateau in effectiveness for several years and certainly biological therapy (approved antiangiogenic agents and tyrosine kinase inhibitors) has slightly improved survival; however, the mortality of NSCLC is very high and survival after development of metastatic disease is less than 2 years. Therefore, new approaches are required to improve current outcomes.

Active-specific immunotherapy is an area of oncology that is rapidly expanding and delivering promising results such as asymptomatic prostate cancer with the use of sipuleucel-T. In the field of lung cancer, there are multiple vaccines focused on creating specific antitumor activity in NSCLC (Table 1).

**The immune system in NSCLC**

The immune system plays an important role in the interaction between cancer and its host. Scientists have long understood that tumors can be recognized by a patient’s immune system. Rare reports dating back to the 1800s have documented spontaneous tumor regression after infectious events. Such regressions, however, are usually seen in only very immunogenic tumors, such as renal cell carcinoma and melanoma.

NSCLC is a notoriously non-immunogenic cancer, or a cancer in which we have been unable to trigger an appropriate immune response for multiple reasons and this characteristic has limited the development of immune therapies for NSCLC. If, however, the immune system can be stimulated to recognize the tumor as an antigen, it can be utilized to specifically attack the tumor. This strategy allows the patient to avoid toxicities, like myelosuppression, neutropenic fever, mucositis, hair loss, and GI disturbance, which arise from indiscriminately destroying all dividing cells with systemic chemotherapy. Therapeutic vaccines have been developed for the treatment of other types of cancers. For example, Sipuleucel-T is a monoclonal antibody vaccine in phase III clinical trials that modulates T cell activity in patients with metastatic melanoma and castrate-resistant prostate cancer.

There is evidence to suggest that a similar approach could be very beneficial to the survival and quality of life of NSCLC patients.

Malignant cells may express or be induced to express antigens that identify themselves to the immune system as foreign invaders that must be removed. Dendritic cells (DCs) and macrophages process and present these antigens in the complex of major histocompatibility (MHC) class I and class II molecules. This antigen presentation results in the activation of immune effector cells, namely cytotoxic T lymphocytes (CTLs). These CTLs then recognize the antigens on tumor cells and induce apoptosis via granzyme and perforin production. In NSCLC, many of the infiltrating T lymphocytes are actually immunosuppressive regulatory T cells (CD25+), which secrete transforming growth factor β (TGF-β) and dampen the immune response to the tumor.

In the presence of TGF-β, the formerly potent CTLs will now tolerate the tumor-associated antigens, rather than causing apoptosis. Tumor cells can also favor tolerant DCs that drive the differentiation of T cells towards the immunosuppressive regulatory T cells, rather than the cytotoxic T cells. Thus, there are many targets that can be utilized to induce immunogenicity of NSCLC.

Active immunotherapy has been proposed as a novel method to palliate metastatic and non-operable NSCLC...
patients and as an adjuvant therapy to surgical resection. A therapeutic vaccine is composed of one or more tumor antigens, and sometimes with an adjuvant that the immune system recognizes as foreign. Such a vaccine induces a powerful and enduring immune response to the specific tumor antigen(s). Via the immune mechanism described above, the tumor antigens are taken up by DCs and CTLs are subsequently activated for tumor destruction.14

Vaccines can either be immune system modulators directed to allow de novo generation of antitumor activity or agents that elicit specific antitumor activity, known as therapeutic cancer vaccines.15 Therapeutic cancer vaccines are classified in either whole-cell vaccines or vaccines that target specific antigens. These vaccines have been developed for all stages of NSCLC and have been studied in Phase II and are currently undergoing Phase III clinical trials (Tables 1 and 2).7,16,17

A good example of a whole cell vaccine is Belagen-pumatucel-L, developed from four different NSCLC cell lines, each with an antisense gene for TGF-β2. There are different vaccines that target specific antigens in the cancer cell, including the melanoma-associated antigen A3 (MAGE-A3; only found in cancer cells) vaccine, while the L-BLP25 and TG4010 vaccines are antigen vaccines that target the Mucin-1 protein. Finally, the CIMAvax vaccine targets EGF and prevents it from binding with its receptor, effectively preventing tumor growth. Each of these vaccines has shown promising results in Phase II trials (Table 1) and offers many potential targets for the directed treatment and improved survival of NSCLC patients (Table 1).5

**Early studies of immunotherapy for lung cancer**

Lung cancer immunotherapy before 1990 focused on nonspecific immune stimulants including Bacille Calmette-Guerin (BCG), thymosin, and Corynebacterium parvum.18 Small cell lung cancer (SCLC) was commonly investigated because it was feasible to treat patients with minimal residual disease following curative chemotherapy and radiation.

Two larger series of patients with lung cancer treated with BCG found improvements in survival compared to historical controls, as well as a survival benefit for intrapleural BCG injection for patients with pleural effusions.19,20 Patients with adenocarcinomas were reported to respond better than those with squamous cell carcinomas.21 Excitement about nonspecific agents was tempered, however, by a randomized study of BCG as adjuvant therapy for SCLC demonstrating no impact on overall survival.22 In addition, a study of preoperative intra-tumoral injection of BCG found no impact on disease-free or overall survival;23 however, both of these randomized trials were underpowered to detect small differences. The role of BCG in lung cancer immunotherapy is now primarily as an adjuvant immune stimulant with autologous tumor or antigen-specific vaccine strategies.24 T cell growth factor thymosin, another nonspecific immune stimulant, was found to have activity in combination with chemotherapy, especially among patients whose immune systems were not activated at the time therapy was initiated.25

Similarly, early studies using the bacterium C. parvum as a systemic antitumor agent for NSCLC demonstrated dose-related tumor responses, but no effect on overall survival.18

During the 1990s, nonspecific immunotherapy was attempted with interleukin (IL)-2 and other cytokines or inflammatory mediators. For example, Schiller et al26 reported a series of 15 patients with advanced lung cancer treated with IL-2 and tumor necrosis factor (TNF)-α. Cardiopulmonary toxicity was common, and there were no significant tumor responses. Similarly, a combination of IL-2 and interferon (IFN)-α demonstrated no benefit.27 A combination of IL-2 and melatonin, on the other hand, demonstrated a clinical benefit (20% partial response, 50% stable disease) in a study of 20 patients.28

**Types of therapeutic vaccines in non-small cell lung cancer**

There are two types of vaccines in NSCLC: passive and active immunization. Passive immunization involves the administration of antibodies, as intramuscular immune globulin derived from pooled human serum or antitoxin derived from serum harvested from immunized animals (Table 3). Passive immunization offers short-term protection to people who have been or will be exposed to a specific pathogen and is typically used by immunocompromised patients who are unable to produce an effective immune response with active immunization.

Active immunization involves the administration of antigens that stimulate the host to produce a primary immune response (usually by inducing B cell proliferation, antibody response, and T cell sensitization; Table 4). If an individual is subsequently exposed to the pathogen against which the vaccine is directed, the exposure results in a secondary response that includes increased proliferation of B cells and formation of antibodies. The secondary response protects the individual from developing disease, ideally for life.
Passive immunizations for NSCLC

Nowadays, there are multiple monoclonal antibodies to treat different types of cancer, such as rituximab for lymphoma and trastuzumab for breast cancer. So far, however, passive immunotherapy has not made an impact on lung cancer.

Trastuzumab (anti-human epidermal growth factor receptor [HER] 2 antibody) has been evaluated for patients with advanced NSCLC. In a Phase II study of 24 patients with HER-2 overexpressing tumors, only one patient had a partial clinical response to therapy. In another study, trastuzumab was tested in combination with chemotherapy for advanced NSCLC. None of the 13 HER2-positive patients in this cohort responded to targeted therapy.29

Another agent that has been developed recently is an antibody targeting the ganglioside fucosyl GM-1. In preclinical studies, this drug was shown to decrease formation of metastatic lung cancer via antibody-dependent cell-mediated cytotoxicity. Antigen-specific radioimmunotherapy has been attempted for SCLC by utilizing bispecific monoclonal antibodies. This was felt to be a promising treatment strategy because SCLC is highly radiosensitive. In one study, anticarinoembryonic antigen (CEA) antibody was attached to a radionucleotide-binding antibody; 3 of 12 patients responded to this treatment.30

Active immunizations for NSCLC

There are different active vaccines for NSCLC, the two most important ones are whole cell vaccines and antigen specific vaccines.

Whole cell vaccines

Belagenpumatucel-L

Belagenpumatucel-L is an allogeneic whole cell vaccine that was created from four different NSCLC cell lines (one squamous cell carcinoma, one large cell carcinoma, and two adenocarcinoma) that were genetically modified to elaborate an antisense oligonucleotide to TGF-β2. Because this vaccine was created from multiple cell lines, it has a wide array of antigens and is thus potentially beneficial in most NSCLC patients. TGF-β suppresses the activity of natural killer cells, CTLs, and dendritic cells, effectively shutting down antitumor immune function. TGF-β also has the capacity to convert immature T cells to immunosuppressive regulatory T cells by inducing the transcription factor Forkhead box P3 (FOXP3). Preclinical studies revealed that antisense inhibition of TGF-β2 expression enhances effector cell-mediated tumor death. High TGF-β2 levels are associated with poor prognosis in NSCLC. Fortunately, Belagenpumatucel-L causes the downregulation of TGF-β2. By decreasing the amount of TGF-β2 in the tumor microenvironment, immunity against the tumor is restored.31

In a Phase II trial by Nemunaitis et al, in 2006, 75 NSCLC patients with stage II–IV disease were randomized to receive intradermal injections with one of three different dosage levels of Belagenpumatucel-L (1.25 × 10^7, 2.5 × 10^7, or 5 × 10^7 cells/injection) either every month or every 2 months, up to a maximum of 16 doses. Study participants were required to have an estimated tumor burden of 125 mL or less excluding bone and nodal disease, but there were no restrictions in regards to previous therapies. Most of these patients (61 of 75) had advanced disease that could not be surgically resected. Fifteen percent of the study participants with advanced diseased showed a partial response to the experimental treatment. The study revealed two important points about this vaccine. First, the patients who received one of the two higher dosage levels (>2.5 × 10^7 cells/injection) had a significantly improved overall survival rate of 47% relative to the overall survival rate of 18% for participants who received the low dosage level (1.25 × 10^7 cells/injection; P = 0.0069). Second, a subgroup analysis performed on those patients that had a partial response along with antibody-mediated response showed a significant increase in the production of interferon-γ, IL-4, and IL-6 (P = 0.014). The overall survival rate of 32.5 months among responders constitutes a statistically significant increase in response compared to patients who did not respond; these control patients had an overall survival of 11.6 months (P = 0.011). Belagenpumatucel-L demonstrated minor toxicity with only one grade 3 adverse event. This was a single patient who developed edema at the injection site. Although another participant developed chronic myelogenous leukemia 5 months after the final cycle of treatment with Belagenpumatucel-L, this event was reportedly unrelated to vaccine administration.32

Based on the promising results of the Phase II trial, the survival, tumor-free, overall, and progression-free (STOP) Phase III randomized placebo-controlled clinical trial was designed to assess whether Belagenpumatucel-L can prolong the overall survival of stage III and IV NSCLC patients by at least three months.3 Patients with stage IIIa/IIIb, or IV NSCLC will receive 18 monthly immunizations (2.5 × 10^7 cells/injection) followed by two booster injections at 3 month intervals. Controls receive best supportive care and placebo injections. To qualify for enrollment, patients must have responded to chemotherapy or had stable disease following a platinum-based chemo regimen. The primary endpoint is overall survival with secondary endpoints of

Antigen specific vaccines
MAGE-A3
MAGE-A3, a melanoma-associated antigen, is a specific tumor antigen that is not found on normal cells. MAGE-A3 is found only in the testis, but it is not presented as an antigen because of the lack of MHC class I molecules in this immune-privileged location. The MAGE-A3 protein is expressed in a variety of cancers, including 35% of NSCLC. MAGE-A3 expression is associated with poor prognosis, and the rate of expression increases as the disease progresses (30% in stage I NSCLC and 50% in stage II NSCLC). MAGE-A3 gene activation occurs early in lung carcinogenesis and this epitope has well-documented CTL immunogenicity. MAGE-A3 is found most frequently in squamous cell carcinoma amongst the NSCLCs. The MAGE-A3 vaccine is an antigen vaccine that consists of a full-length MAGE-A3 protein complexed to part of the \textit{Hemophilus influenzae} protein D, packaged with lipid adjuvants. It has been designed for use in the postoperative setting in patients with stage I, II, or IIIa cancer. In patients who have undergone surgical resection, the clinical usefulness of these vaccines is maximized because of the lower

postoperative tumor burden and the more direct access vaccine has to all tumor cells. In the Phase II trial by Vansteenkiste et al in 2007, 182 MAGE-A3+ patients with surgically resected stage Ib and II NSCLC received induction with five doses of either MAGE-A3 300 µg vaccine or placebo every 3 weeks and then maintenance therapy of eight doses or placebo every 3 months. Follow-up at 28 months revealed improved disease-free interval (primary endpoint) in the treatment group with a hazard ratio of 0.74 (95% confidence interval [CI] 0.44–1.2; \( P = 0.107 \)). In study participants with stage Ib/II resected NSCLC, treatment with the MAGE-A3 vaccine decreased the risk of recurrence by 25% (hazard ratio [HR] = 0.75; 95% CI 0.46–1.23). Moreover, in those participants with documented MAGE-A3 expression, treatment decreased relative risk of recurrence by 43% (HR = 0.57; 95% CI 0.25–1.34). Although these results did not reach statistical significance, a clear survival benefit was observed in this trial. After a median follow-up of 44 months, only 30.3% of the treatment group experienced relapse, compared to a rate of 41.7% in the control group. The vaccine was well-tolerated with only mild flu-like symptoms and injection site reactions.

Following the results of the Phase II trial, MAGE-A3 as adjuvant non-small cell lung cancer immunotherapy (MAGRIT), the largest Phase III lung cancer study in history, was designed and is ongoing. MAGRIT is a randomized, double-blinded, placebo-controlled study that evaluates the use of the MAGE-A3 vaccine as adjuvant therapy. Study participants have completely resected stage Ib, II, or IIa NSCLC, and are MAGE-A3+ by polymerase chain reaction (PCR). The study also compares the efficacy of MAGE-A3 vaccine in participants who underwent resection and adjuvant chemotherapy with a control group who solely underwent resection prior to vaccination. Patients in the study are assigned in a 2:1 ratio to the treatment group versus the placebo group. Five doses are to be administered at 3-week intervals for induction and followed by maintenance therapy with vaccination every 12 weeks. The primary objective is disease-free survival in MAGE-A3 treatment after complete resection. Secondary objectives include efficacy in the overall population and efficacy in patients who did not receive adjuvant chemotherapy. A recent meta-analysis on 7,626 patients from 25 different randomized trials revealed a pronounced correlation between disease-free survival and overall survival. These results lend further credibility to the use of disease-free survival rates as a primary endpoint. The MAGRIT trial is ongoing, with a planned enrollment of 2,270 patients, and has an estimated completion date of October 2016.

**Mucin-1 targets: L-Blp25 and Tg4010**

Mucin-1 (MUC-1) is a transmembrane protein normally found on the apical surface of cells. In many malignancies, MUC-1 is found to be overexpressed and under-glycosylated or aberrantly glycosylated. This deranged glycosylation can unmask epitopes on the peptide core that may act as tumor-associated antigens. MUC-1 is an oncogene common to breast, lung, colon, pancreatic, and ovarian cancers that is believed to be involved in tumor cell migration and resistance to chemotherapy-related apoptosis. High serum MUC-1 levels are associated with poor survival, presumably due to immune suppression in the tumor microenvironment. MUC-1, abnormally expressed in almost half of all NSCLC, has been proven to inhibit physiologic T cell proliferation. This activity of MUC-1 decimates the host’s antitumor immune response, which normally relies on CTL tumor cell killing. MUC-1 oncogene immune evasion by CTL inhibition is confirmed by the administration of IL-2, which circumvents this process and stimulates T cell proliferation. The glycosylation pattern on the abnormally expressed MUC-1 in NSCLC makes it an attractive target for immune therapy.

L-Blp25 (Stimuvax) is a 20-amino acid peptide with low-dose cyclophosphamide in a liposomal vehicle. The cyclophosphamide is used to interfere with the number and function of CD25 regulatory T cells in the tumor microenvironment. The liposomal vehicle enhances tumor-associated antigen recognition. This synthetic vaccine targets the exposed core of MUC-1 when aberrantly glycosylated, which induces immune response against the tumor cell. Antigen-specific CTL proliferation and production of IFN-γ occur in response to vaccine administration.

A randomized Phase II trial was conducted by Butts et al in 2007 on 171 stage IIIb or IV NSCLC patients after response or stable disease to first-line chemotherapy. Participants were then randomized to receive either L-Blp25 with best supportive care or, alternatively, best supportive care alone. Patients undergoing the treatment regime received a single dose of cyclophosphamide 300 mg/m² three days before administration of the vaccine, followed by eight doses of L-Blp25 vaccine (1000 µg), given weekly. Maintenance vaccinations could be given to the study group every 6 weeks thereafter, at the discretion of the investigator, until the patient exhibited disease progression. The primary objective was median overall survival, which was 17.2 months in the treatment group versus 13.0 months in the control group (adjusted HR = 0.739; 95%
CIMAvax EGF vaccine

Epidermal growth factor (EGF) and its cell receptor are overexpressed in many carcinomas, including NSCLC. EGF binds to its receptor on cells and provides signaling for cell growth and proliferation. The EGF receptor (EGFR) pathway inhibitors like monoclonal antibodies and tyrosine kinase inhibitors have shown great efficacy in clinical practice. The EGF vaccine CIMAvax was developed in Cuba with recombinant human EGF, P64K Neisseria meningitides carrier protein, and immunoadjuvant Montanide ISA 51. Administration of the vaccine causes production of anti-EGF antibody against EGF. This prevents EGF from binding to its receptor, inhibiting tumor growth.

Three pilot studies were initially conducted to optimize the formulation of the vaccine. Pooled data of the 83 patients with stage IIIb/IV NSCLC in these three studies revealed that 83% of vaccinated patients at least doubled their baseline anti-EGF antibody titers, referred to as seroconversion. Theoretically, higher antibody titers correlate with better response to treatment, so these studies sought to create a vaccine that induces the highest possible anti-EGF antibody titer. Results revealed that Montanide ISA 51 was an effective immunoadjuvant and that pre-treatment with cyclophosphamide enhances antibody titer response to the vaccination. The combined results of the three trials revealed that patients with seroconversion had an 11.1 month overall survival versus a 5.7 month overall survival in participants who did not.
seroconvert \( (P = 0.005) \). The data also revealed that patients who achieved antibody titers above the median (median maximal antibody titer 1:4,000) had a survival advantage over participants with titers below the median (12.2 months versus 8.1 months; \( P = 0.036 \)). During the course of these studies, researchers recognized that antibody titers waned relatively quickly without subsequent vaccination, but also that antibody titers could be easily recovered with the use of booster vaccines.\(^{47}\)

A Phase II study by Neninger et al\(^ {48} \) on CIMA Vax in 2003, involved 80 participants with stage IIIb or IV NSCLC who had received first line chemotherapy prior to the study. Participants were randomized to receive either CIMA Vax and best supportive care or to receive best supportive care alone. Those in the experimental group received priming with low dose cyclophosphamide, followed by 50 \( \mu \)g doses of EGF vaccine administered on days 1, 7, 14, 28, and then monthly. Serum EGF levels were measured in both groups and were found to be lower in the vaccine group, confirming that CIMA Vax induces production of the anti-EGF antibodies that lower serum EGF concentration. Median survival was improved in the experimental group (6.5 months versus 5.3 months; \( P = 0.098 \)). Although these results were not significant, a subgroup analysis amongst patients under 60 years old did reveal a significant survival advantage in the experimental group (11.6 months versus 5.3 months; \( P = 0.0124 \)). Patients with antibody titers >1:4,000 also exhibited a statistically significant improvement in survival (11.7 months versus 3.6 months; \( P = 0.002) \).\(^ {3} \) Toxicity from the vaccine was minimal in this trial, including mild flu-like symptoms and injection site reactions.\(^ {48} \)

A Phase III trial was done to evaluate overall survival with the use of CIMA Vax in stage IIIb or IV NSCLC patients. Participants in the experimental group received CIMA Vax and best supportive care after having received first-line chemotherapy. Participants in the control group received best supportive care and a placebo after first-line chemotherapy. Participants were divided into two subgroups: those younger than 60 and those older than 60. This Phase III trial is now ongoing to examine the efficacy of therapeutic vaccination in a larger number of patients with all stages of NSCLC.

Further encouraging results from these studies could very well result in the clinical approval of therapeutic vaccines to combat NSCLC.

**Conclusion**

Patients with NSCLC face a dismal prognosis at the time of diagnosis due to an advanced and aggressive disease, coupled with the limited available treatment options. Early studies of active immunotherapy have exhibited promising results for use with NSCLC, especially in advanced disease where the overall survival rate has, historically, been very grim. While therapeutic vaccination may not be a panacea, it could serve as a vital adjunct to traditional surgical and chemotherapeutic treatment regimens as we see in the case of the MAGE 3 vaccine for adjuvant therapy or in the case of CIMA Vax where it is used with chemotherapy in advanced disease patients.

The identification of better antigenic targets, addition of immune-stimulating adjuvants, and production of improved delivery mechanisms has resulted in a group of vaccines that appear able to elicit an effective immune response against tumor cells. This has been a major change in the area of cancer immunology where lung cancer vaccines have never been a popular topic. Phase II studies show that these vaccines can produce statistically significant improvements in the PFS or overall survival for patients, irrespective of the stage of the patient’s disease. These vaccines have demonstrated low toxicity together with improved survival and an enhanced quality of life relative to the baseline prognosis. As a result of these studies, for first time in the history of lung cancer and immunotherapy, several Phase III trials are ongoing to examine the efficacy of therapeutic vaccination in a larger number of patients with all stages of NSCLC.

Further encouraging results from these studies could very well result in the clinical approval of therapeutic vaccines to combat NSCLC.
