Abstract: The proteasome inhibitor bortezomib (BZ) has shown promising results in some types of cancer, but in others it has had minimal activity. Recent studies have reported enhanced efficacy of BZ when combined with hyperthermia. However, the use of magnetic nanoparticles to induce hyperthermia in combination with BZ has not been reported. This novel hyperthermia modality has shown better potentiation of chemotherapeutics over other types of hyperthermia. We hypothesized that inducing hyperthermia via magnetic nanoparticles (MFH) would enhance the cytotoxicity of BZ in BZ-sensitive and BZ-resistant cancer cells more effectively than hyperthermia using a hot water bath (HWH). Studies were conducted using BZ in combination with MFH in two BZ-sensitive cell lines (MDA-MB-468, Caco-2), and one BZ-resistant cell line (A2780) at two different conditions, ie, 43°C for 30 minutes and 45°C for 30 minutes. These experiments were compared with combined application of HWH and BZ. The results indicate enhanced potentiation between hyperthermic treatment and BZ. MFH combined with BZ induced cytotoxicity in sensitive and resistant cell lines to a greater extent than HWH under the same treatment conditions. The observation that MFH sensitizes BZ-resistant cell lines makes this approach a potentially effective anticancer therapy platform.

Keywords: magnetic fluid hyperthermia, hot water hyperthermia, BZ, enhanced cytotoxicity, thermal sensitization

Introduction

The proteasome, a multisubunit proteinase machinery, is in charge of degrading 80%–90% of all nuclear and cytosolic proteins in cells¹–³ and plays an essential role in regulating the intracellular concentration of specific proteins, thereby maintaining homeostasis within the cell.¹,⁴,⁵ Inhibition of the 26S proteasome prevents this targeted proteolysis, which can affect multiple signaling cascades within the cell, leading to cell death.¹,⁶ As such, proteasome inhibition has become an attractive target for cancer treatment.⁷

Bortezomib (BZ), a drug approved by the US Food and Drug Administration, is a reversible inhibitor of the chymotrypsin-like activity of the 26S proteasome in mammalian cells. It has been tested as a potential therapeutic agent for the treatment of several types of cancer including breast, colon, ovarian, lung, and certain hematologic neoplasms.⁸ Unfortunately, some of these types of cancer do not respond to its therapeutic effect, because they have intrinsic or acquired BZ resistance.⁹–¹³ The reason for this phenomenon is still unknown, but some molecular mechanisms have been proposed. de Wilt et al demonstrated that intrinsic BZ resistance of non-small-cell lung cancer is related to increased proteasome activity.¹⁴ On the other hand, acquired resistance...
was associated with mutation of the β5 subunit, which is the proteasome subunit where BZ binds. Overexpression of antiapoptotic protein Bcl-2 and heat-shock proteins 27, 70, and 90 is also considered a mechanism of acquired BZ resistance.

Recent studies have provided evidence of enhanced efficacy of BZ when used in combination with hyperthermia. Xu et al showed that hyperthermia using a water bath sensitized resistant breast cancer cells to BZ, resulting in enhanced cell death. Similar observations were made with HT1080, HeLa, H1299, and HCT116 cells exposed to BZ and hyperthermia. The mechanism by which hyperthermia enhances BZ cytotoxicity has not been elucidated. However, protein unfolding and subsequent aggregation induced by hyperthermia is considered one of the mechanisms by which hyperthermia sensitizes cells to proteasome inhibition.

Although in vitro studies of hyperthermia with BZ have shown promising results, translation to the clinic has been limited due to challenges regarding application of hyperthermia as a treatment modality. These include avoidance of nonspecific damage to adjacent tissues, occurrence of tachycardia and malaise, and a detrimental impact on tissue metabolism, blood flow, organ function, and tissue repair. For these reasons, alternative hyperthermia application approaches are being actively pursued.

The use of magnetic nanoparticles for localized thermal oncology is a novel and attractive approach. This approach, commonly called magnetic fluid hyperthermia (MFH), takes advantage of the deposition of thermal and mechanical energy by magnetic particles under an applied alternating magnetic field, resulting in local heating of cancerous tissue. Recently, we have demonstrated that application of MFH to treat a human epithelial colorectal adenocarcinoma cell line (Caco-2) was more effective in reducing cell viability when compared with hot water hyperthermia (HWH) at similar thermal doses. Also, combination treatment using cis-diamminedichloroplatinum(II) and MFH induced significant cytotoxicity in the Caco-2 cell model, and was more effective than a combination of the drug with hyperthermia using a hot water bath. Subsequently, it was demonstrated that one of the mechanisms explaining why MFH is significantly more effective in combination with cis-diamminedichloroplatinum(II) than HWH is an increase in membrane fluidity which allows higher intracellular drug accumulation.

Our past work motivated us to search for other anticancer drugs that could potentially be enhanced by the application of MFH, particularly in cases of intrinsic or acquired chemoresistance. Given the expectation that delivery of thermal energy to the interior of a cell could result in enhanced protein denaturation, we hypothesized that proteasome inhibitors in combination with MFH should possess enhanced cytotoxicity that is greater than each individual treatment. In order to test this hypothesis, dose response curves and proteasome activity curves, as a function of BZ concentration were conducted. The following cell lines were selected to conduct the experiments: human epithelial breast carcinoma cells (MDA-MB-468), heterogeneous human colorectal adenocarcinoma cells derived from colon carcinoma (Caco-2), and human epithelial ovarian cancer cells established from the tumor tissue of an untreated patient (A2780). Two of these are BZ-sensitive (MDA-MB-468, Caco-2) and one is BZ-resistant (A2780). The cell response to BZ in combination with MFH at two different conditions (43°C for 30 minutes and 45°C for 30 minutes) was then measured and the combined cytotoxicity was compared with that of HWH and BZ. Results indicated that enhancement of cytotoxicity between MFH and BZ is greater than the effect produced by HWH and BZ at similar thermal doses. Our results confirm the effectiveness of MFH for potentiation of BZ, even in cell lines that show intrinsic resistance to this drug, making this an attractive approach for enhancing the effectiveness of a drug already approved by the US Food and Drug Administration.

Materials and methods

Cell culture

MDA-MB-468 and Caco-2 cells were obtained from the American Type Culture Collection (Manassas, VA, USA). The cells were cultured in 75 cm² flasks (Costar, Corning, NY, USA) using Dulbecco’s modified Eagle’s medium (Sigma, St Louis, MO, USA) containing 10% fetal bovine serum (Invitrogen, Carlsbad, CA, USA), 1% nonessential amino acids (Invitrogen), 100 units/mL of penicillin (Sigma), and 100 µg/mL of streptomycin (Sigma), and supplemented with 2 mM L-glutamine and 24 mM sodium bicarbonate. The cells were maintained at 37°C, 95% relative humidity, and 5% CO₂. A2780 cells were donated by Dr Anil K Sood from the MD Anderson Cancer Center, Houston, TX, USA. They were cultured in Roswell Park Memorial Institute medium (Sigma) with 15% fetal bovine serum and 0.1% gentamicin (Sigma) at 37°C under 5% CO₂.

Drug

BZ (LC Laboratories, Woburn, MA, USA) was dissolved in dimethylsulfoxide (Sigma), aliquoted, and stored at ~20°C.
Aliquots were thawed and diluted in Dulbecco’s modified Eagle’s medium before use.

Synthesis of iron oxide nanoparticles
Iron oxide nanoparticles were synthesized by the coprecipitation method and coated with carboxymethyl dextran, as described previously. An aqueous iron solution (Fe$_{39}$:Fe$_{57}$) and an ammonium hydroxide solution were mixed at 80°C. The pH of this reaction mixture was maintained at 8.0 while stirring for one hour with bubbling nitrogen. After this reaction period, the solution was centrifuged at 1,500 rpm for 5 minutes, the supernatant was discarded, and the magnetic nanoparticles were peptized with tetramethyl ammonium hydroxide (1 M). The peptized nanoparticles were dried at 65°C using a vacuum oven. Next, 1.125 g of peptized iron oxide nanoparticles were functionalized with 3-aminopropyltriethoxysilane (APS) in a solution containing 75 mL of dimethylsulfoxide, 5 mL of APS, 1.25 mL of water, and 100 μL of acetic acid. This solution was stirred for 36 hours in a shaker at 150 rpm and room temperature. At the end of the reaction, the nanoparticles were washed four times with ethanol by centrifugation and left to dry at room temperature. The iron oxide nanoparticles coated with APS were then functionalized with carboxymethyl dextran via reaction with N,N-(3-dimethylaminopropyl)-N'-ethylcarbodiimide hydrochloride (EDC)/N-hydroxysuccinimide (NHS) in order to form covalent bonds between APS and carboxymethyl dextran. This reaction was achieved by mixing a solution containing 1 g of carboxymethyl dextran, 10 mL of deionized water, 12.25 mg of EDC, and 7.25 mg of NHS at pH 4.5–5 with 0.1 g of IO-APS dissolved in 10 mL of deionized water at pH 4.5–5. This mixture was stirred at 150 rpm for 36 hours at room temperature. After this reaction period, the nanoparticles were washed three times with ethanol by centrifugation and left to dry in a vacuum oven at 65°C.

The nanoparticles were sterilized at a temperature of 121°C and 15 psi for 60 minutes before the in vitro experiments. They were then characterized and suspended in Dulbecco’s modified Eagle’s medium prior to the experiments. The final particle concentration was 3.848 mg particles per mL (0.5 mg IO/mL).

Characterization of nanoparticles
The physical size and morphology of the iron oxide nanoparticles were determined using an energy-filtered transmission electron microscope (LEO 922 Omega, Carl Zeiss Meditec AG, Jena, Germany) at 200 kV. The hydrodynamic diameter of the synthesized and functionalized nanoparticles suspended in deionized water was determined by dynamic light scattering using a particle size analyzer (BI-90 Plus, Brookhaven Instrument Corporation, Holtsville, NY, USA). Inorganic core content was estimated using a thermogravimetric analyzer (TGA/DSC1, MettlerToledo Inc, Columbus, OH, USA). The magnetic properties of the nanoparticles were determined using a SQUID magnetometer (MPMS XL-7, Quantum Design Inc., San Diego, CA, USA). The specific absorption rate of the iron oxide nanoparticles was obtained by placing a solution of nanoparticles in deionized water at a concentration of 0.5 mg IO/mL in an induction heater (HFI 3 KW RF heating system, RDO Induction LLC, Washington, NJ, USA) with magnetic field intensities ranging from 24.18 kA/m to 34.73 kA/m. The specific absorption rate is reported as watt per gram of iron oxide.

BZ dose-response curve
MDA-MB-468 and Caco-2 cells were seeded in 96-well plates (Fisher Scientific, Suwanee, GA, USA) and allowed to adhere for 48 hours in Dulbecco’s modified Eagle’s medium solution. A2780 cells were allowed to adhere for 24 hours in Roswell Park Memorial Institute medium. These time periods were chosen to ensure that the cells were in log phase growth before treatment. After this incubation period, the cells were exposed to varying concentrations of BZ (2–1,000 nM) for 48 hours. The cells were then washed twice with phosphate-buffered saline (Sigma), stained with Cell Titer Blue™ (Promega, Madison, WI, USA) and analyzed fluorometrically (Spectra MAX Gemini EM, Molecular Devices, Sunnyvale, CA, USA).

Proteasome activity
Cells were seeded in 96-well plates (10,000 cells per well) and allowed to adhere in medium solution as described before. Adhered cells were exposed to various concentrations of BZ (2–1,000 nM) for 3 hours. Next, 100 μL of Proteasome-Glo™ Chymotrypsin-Like Assay (Promega), containing a substrate which luminesces when recognized and degraded by the proteasome, was added per well and allowed to react at room temperature for 15 minutes in the dark. After this period, luminescence measurements were made in a spectrofluorimeter (Spectra MAX Gemini EM).

Combined hyperthermia treatment
Approximately 5 × 10^5 cells were transferred to 10 mL glass tubes. Cells to be treated by HWH were suspended in 2.5 mL of complete medium with and without BZ. Next, samples in the presence of BZ were left in the incubator for 3 hours to promote proteasome inhibition before hyperthermic
treatment. After pretreatment, the samples were placed in a temperature-regulated water bath for 30 minutes at 43°C or 45°C. Cells to be treated by MFH were suspended in 2.5 mL of DMEM solution with or without BZ, concomitantly with a concentration of 3.8 mg/mL of autoclaved carboxymethyl dextran-coated magnetite nanoparticles. Samples containing BZ were incubated for 3 hours prior to applying the alternating magnetic field. The samples were then placed in an induction heater coil (HFI 3 KW RF heating system) and magnetically heated to 43°C or 45°C for 30 minutes. A magnetic field of 29.39 kA/m or 34.73 kA/m was applied to maintain the sample temperature at 43°C or 45°C, respectively. A frequency of 233 kHz was applied at both temperature conditions. Control tubes had the same dimethylsulfoxide concentration as the experimental group (0.1%) but remained in the incubator at 37°C. After treatment, 100,000 cells were transferred to six-well plates (Fisher Scientific) exposing cells continuously to the drug to maintain a constant proteasome inhibition for an additional of 48 hours at 37°C and 5% CO₂. After incubation, the cells were trypsinized and cell viability was measured using the trypan blue exclusion method (Sigma). Our previous work using anticancer drugs such as cisplatin in combination with hyperthermia has shown similar tendencies between viability ratio and surviving fraction using trypan blue and clonogenic survival fraction respectively. For this reason, we only determined the viability ratio in this study.

Statistical analysis
Unless otherwise stated, the sample size was n=3. Statistical analyses were conducted using the Student’s t-test (two-tailed distribution, two samples with unequal variances). Differences were considered to be statistically significant at P<0.05.

Results
Nanoparticle characterization
The cluster size of the synthesized magnetic nanoparticles determined by transmission electron microscopy was approximately 69±4 nm, consisting of primary nanoparticles 11 nm in diameter (Figure 1A shows a representative image of a cluster of particles). The hydrodynamic diameter of the iron oxide nanoparticles coated with carboxymethyl dextran determined by dynamic light scattering was ~70 nm (Figure 1B), with some aggregates of ~300 nm visible in the volume-weighted diameter distribution. The inorganic mass was determined by thermogravimetric analysis (Figure 1C), and was determined to be 14% by weight. The specific absorption rate of the nanoparticles was 46.9 W/g of iron oxide at a magnetic field amplitude of 34.73 kA/m and frequency of 233 kHz. Finally, SQUID magnetization measurements showed the nanoparticles to be superparamagnetic, with a saturation magnetization of ~58 Am²/kg at 300 K (Figure 1D). The nanoparticles used in this study were not cytotoxic at a concentration of up to 0.5 mg IO/mL (data not shown).

Sensitivity of cancer cells to BZ
Recent studies have shown that the sensitivity of cancer cells to BZ is cell line-dependent.⁸,⁹,¹²,¹³ To assess the sensitivity of different cancer cell lines to the therapeutic effect of BZ, the viability of three different cell lines (Caco-2, MDA-MB-468, and A2780) was determined after exposing the cells to increasing concentrations of BZ for 48 hours.

As Figure 2 shows, the Caco-2 and MDA-MB-468 cell lines were significantly more sensitive to BZ than A2780 cell lines, showing half maximal inhibitory concentrations of 15 nM, 9 nM, and 250 nM, respectively (Figure 2). This result confirms that A2780 has intrinsic BZ resistance. For subsequent experiments, the maximum BZ concentration was kept at 100 nM, because this is the maximum concentration clinically achieved in the plasma of patients treated with BZ.¹³

Proteasome activity curves
BZ is a reversible proteasome inhibitor and a modified dipeptidyl boronic acid specifically designed to fit the active sites of the proteasome.⁹ Proteasome inhibition is a function of exposure time and concentration of the drug. To evaluate the effect of hyperthermia in combination with BZ for BZ-sensitive and BZ-resistant cells under the same conditions, it is necessary to choose a BZ concentration that achieves the same proteasome inhibition before applying hyperthermic treatment. Therefore, proteasome inhibition curves, as a function of BZ concentration, were determined by exposing cells to the drug for 3 hours. Proteasome activity was measured after this incubation period.

The proteasome activity curve for Caco-2 cells (Figure 3) illustrates that, above 10 nM BZ, proteasome activity does not change further for this exposure time. Proteasome inhibition is approximately 57% at 6 nM BZ. Proteasome activity also decreases in MDA-MB-468 and A2780 cell lines as a function of drug concentration. At 10 nM BZ, the proteasome activity is 59% for MDA-MB-468, while for A2780 at 30 nM the proteasome activity is 56%. It was observed that A2780 cells showed greater proteasome activity than the other cell lines at a given concentration of BZ. In order to verify enhanced
MFH enhances bortezomib cytotoxicity

In an effort to assess this enhanced cytotoxicity, studies using BZ in combination with MFH in two BZ-sensitive (MDA-MB-468, Caco-2) and one BZ-resistant (A2780) cancer cell line were performed and compared with potentiation using HWH. Cells were pretreated with BZ for 3 hours, followed by exposure to hyperthermic treatment for 30 minutes at 43°C or 45°C. To achieve this, HWH samples were placed in a water bath at the target temperature for 30 minutes and MFH samples were placed in an alternating magnetic field of sufficient amplitude to achieve temperatures of 43°C (29.39 kA/m) and 45°C (34.73 kA/m) for 30 minutes. Experiments with...
a similar target temperature had similar temperature-time profiles, hence the samples were subjected to similar thermal doses as quantified using the cumulative equivalent minutes dose metric of Dewey et al. After treatment, the cell samples were allowed to recover for a period of 48 hours. Cell viability was then measured by cell counting. BZ concentrations were chosen individually for each cell line based on the amount of drug that would result in a similar proteasome inhibition (6 nM for Caco-2, 10 nM for MDA-MB-468, and 30 nM for A2780).

Enhanced cytotoxicity was evident when BZ was combined with either type of hyperthermic treatment (Figure 4). Cell death was not observed when Caco-2 cells were exposed to 6 nM BZ for as long as 48 hours at 37°C (Figure 4A). However, when BZ was combined with hyperthermia, this resulted in a significant decrease in cell viability, as shown by the results at 43°C (89%±5.6% reduction for BZ + MFH and 60%±10% reduction for BZ + HWH, P<0.05) and 45°C (–99%±1.2% reduction for BZ + MFH and 94%±2.3% reduction for BZ + HWH, P<0.05). Consistent with prior observations, MFH showed significantly more cell death than HWH for both temperature conditions. Similarly, both types of hyperthermia enhanced BZ cytotoxicity in MDA-MB-468 cells (Figure 4B). Cells treated with MFH or HWH in combination with BZ showed more cell death when compared with cells treated with BZ alone at 37°C. Again, MFH was significantly more effective in inducing cell death than HWH under the same temperature conditions, as shown by the results at 43°C (76%±7% reduction for BZ + MFH and 55%±8% reduction for BZ + HWH, P<0.05) and 45°C (–88%±2% reduction for MFH + BZ and 78%±4% reduction for HWH + BZ, P<0.05). Finally, as previously noted, A2780 cells were resistant to BZ, with approximately 60%±4% of cells viable even at 100 nM BZ (Figure 4A). At 30 nM BZ when treated in an incubator, these cells demonstrated no significant cytotoxic response. Interestingly, the effect of BZ was greatly enhanced in the presence of hyperthermia, with MFH treatment showing the greatest response (Figure 4C). At 43°C, cell death was evident (91%±4.9% reduction for BZ + MFH and 70%±10% reduction for BZ + HWH, P<0.05). However, when hyperthermia was applied for 30 minutes at 45°C to pretreated samples with BZ, almost complete eradication of cell viability was observed (–99.7%±0.6% reduction for BZ + MFH and 98%±0.5% reduction for BZ + HWH, P<0.05). Taken together, these results demonstrate enhancement of cytotoxicity by BZ with hyperthermia in both sensitive and resistant cell lines and that MFH is more effective than HWH at enhancing BZ cytotoxicity under the same temperature conditions.

**Discussion**

Caco-2 and MDA-MB-468 cells exhibited greater sensitivity to BZ, while A2780 showed a minimal response to BZ, with half maximal inhibitory concentrations of 15 nM, 9 nM, and 250 nM, respectively. This result suggests that the A2780 cell line possesses intrinsic BZ resistance, while Caco-2 and MDA-MB-468 are sensitive to the therapeutic effect of BZ. Although it was to be expected that the response to BZ would be cell type-dependent, this expectation had not been tested for Caco-2, MDA-MB-468, and A2780 cell lines before. This difference in sensitivity to proteasome inhibitors remains poorly understood.

**Figure 2** Dose-response curve for MDA-MB-468, Caco-2, and A2780 cell lines. Cells were exposed to BZ concentrations of 2–1,000 nM for 48 hours. Error bars represent the standard error of eight independent experiments.

**Figure 3** Proteasome activity for MDA-MB-468, Caco-2, and A2780 cell lines treated with different concentrations of BZ (2–1,000 nM) for 3 hours of exposure time. Error bars represent the standard error of three independent experiments.
understood. However, some studies have reported that intrinsic BZ resistance is related to high proteasome activity, implying that BZ-resistant cell lines need a higher BZ concentration to produce the same proteasome inhibition compared with BZ-sensitive cell lines. For example, Xu et al demonstrated that the proteasome activity of BZ-sensitive cells was less than that of BZ-resistant cells under the same conditions.

Proteasome activity curves were determined in order to assess the effect of BZ concentration in all the cell lines. Proteasome activity results revealed that the A2780 cell line, which is resistant to BZ as reported in Figure 2, demonstrated higher proteasome activity than the other two BZ-sensitive cell lines (Figure 3). This result is consistent with reports in the literature mentioned above. It is known that hyperthermia can sensitize cells to some anticancer drugs, thereby enhancing their efficacy. This has been attributed to cellular events triggered by hyperthermia, such as changes in membrane fluidity which produce alterations in intracellular drug concentration, cytoskeletal, lysosomal and endoplasmic reticulum changes, inhibition of repair enzymes, impairment of RNA/DNA synthesis, unfolding, and subsequent protein aggregation. The way in which hyperthermia is applied can intensify some of these cellular events.
In this study, we tested the effect of hyperthermia induced in two different ways (using a water bath and using magnetic nanoparticles) in combination with BZ in cells sensitive and resistant to BZ. To evaluate the effect of hyperthermia in combination with BZ under the same conditions, we used a BZ concentration that resulted in a similar proteasome inhibition in all cell lines prior to application of hyperthermia. Our results confirm that hyperthermia enhanced the effectiveness of the drug in all cell lines. We observed that MFH in combination with BZ produced more cell death than HWH under the same conditions. Although BZ-sensitive and BZ-resistant cells showed similar levels of proteasome inhibition, thermal sensitization induced by MFH in combination with BZ in cells resistant to BZ resulted in significant cell death.

The mechanisms of the enhanced cytotoxicity seen with MFH and BZ are yet to be elucidated. A recent study by our group demonstrated that MFH induced significant membrane fluidity with better subsequent intracellular accumulation of cisplatin. While the therapeutic effect of cisplatin is limited by transport into the cell, BZ does not appear to have this limitation. BZ has rapid effects on the cell, as shown by pharmacokinetic and pharmacodynamic evaluation. Additionally, several studies have suggested that BZ is not affected by the efflux pumps involved in multidrug resistance. However, it is possible that the membrane fluidity induced by MFH can enhance intracellular accumulation of BZ, and we will explore this possibility in future research.

It is known that hyperthermia (40°C–46°C) causes proteins to unfold, exposing hydrophobic groups that can interact to form aggregates. Recent studies have shown that hyperthermia using a water bath interrupts protein homeostasis in the cell. Taking into account the fact that MFH produces marked effects on the cell as shown by recent studies, one potential cause of this enhanced cytotoxicity could be related to increased production of unfolded proteins and their subsequent aggregation induced by heat delivered by the magnetic nanoparticles, drastically affecting protein homeostasis.

Overall, our results are significant because they demonstrate the enhanced potential of MFH to sensitize resistant and nonresistant cancer cells to the drug BZ. Future work will explore possible causes of this enhanced potentiation, such as interruption of protein homeostasis, differences in uptake of magnetic nanoparticles, and morphologic changes induced by hyperthermic treatments.

Conclusion

Our findings demonstrate that combined treatment of BZ and MFH results in greater cell death in BZ-sensitive and BZ-resistant cells, as compared with MFH or BZ alone, or BZ in combination with HWH. The fact that MFH induced greater BZ cytotoxicity than HWH in BZ-sensitive and BZ-resistant cancer cell lines makes it an attractive method for inducing local hyperthermia without causing discomfort and the side effects associated with other types of hyperthermia. Additionally, the combination of MFH and BZ could enable treatment of cancers that are sensitive and resistant to the proteasome inhibitor BZ. We believe that this enhanced potentiation between MFH and BZ is due to denaturation of proteins and their subsequent aggregation caused by the heat dissipated by the magnetic nanoparticles in MFH. Future studies will be focused on exploring the mechanisms of potentiation between MFH and BZ and translation to animal models.
