Background: Dichloroacetate (DCA) is one of the new, promising anticancer drugs. DCA restores normal mitochondrial function and enables cancer cells to undergo apoptosis. In addition, DCA was found to modulate certain signaling pathways involving some transcription factors. The latter encouraged us to study DCA immunomodulatory activity on cytokines and their association with increasing DCA cancer cell cytotoxicity.

Methods and results: Cell viability assay was used to determine the effect of different concentrations of DCA on the survival of 3-methylcholanthrene (MCA) fibrosarcoma cell line. DCA decreased the percent survival of MCA fibrosarcoma in a dose-dependent manner (P<0.01). Furthermore, this percent survival was further reduced when MCA fibrosarcoma cells were cocultured with mouse spleenocytes. The latter was observed at 10 mM DCA (P<0.01), and the inhibitory concentration at 50% dropped from 23 mM to 15.6 mM DCA (P<0.05). In addition, DCA significantly enhanced interferon (IFN)-γ but not interleukin (IL)-17 production levels in unstimulated and stimulated mouse spleen cells. To investigate the mechanism of DCA on IFN-γ production, DCA cytokine modulatory effect was tested on unstimulated macrophages, T-cells, and natural killer cells. DCA significantly increased IL-12 production from macrophages but did not modulate the production of IFN-γ from either T-cells or natural killer cells. Moreover, the DCA-enhancing effect on IFN-γ production was reversed by anti-IL-12 antibody. Also, the DCA cytokine modulatory effect was tested in vivo after inducing mouse skin inflammation using phorbol 12-myristate 13-acetate (PMA). DCA restored PMA-lowered IFN-γ and IL-12 levels and normalized PMA-increased transforming growth factor-β level, but it inhibited IL-10 levels even further (P<0.05).

Conclusion: DCA has immunomodulatory activity, mainly via activation of the IL-12–IFN-γ pathway and is able to modulate cytokines toward T helper 1 lymphocyte function. These DCA immunomodulatory effects are promising and further investigations are required to develop protocols for its use in cancer treatment.

Keywords: dichloroacetate, fibrosarcoma, cytokines, IL-12, IFN-γ, inflammation

Introduction

Cancer cells generally rely on anaerobic respiration for energy production,1 which leads to lactate formation, thus making the tumor microenvironment more acidic. Such acidity increases cancer cell chemoresistance, suppresses apoptosis, and facilitates mobility and metastasis.1,2 Although reoxygenation via neovascularization mechanisms of solid tumors occur, glycolysis and its byproducts persist.3–4 It was found to inhibit pyruvate dehydrogenase kinase (PDK), which thereby enables pyruvate dehydrogenase
to facilitate pyruvate entering the mitochondria for oxidative phosphorylation. In other words, DCA enables the cell to go through metabolic respiration rather than lactate formation.1–8 Thus, it was thought that DCA could reduce glycolysis-related effects and act as an anticancer drug.

In 2007, Bonnet et al released the first scientific evidence identifying DCA as a potential anticancer compound.2 In comparison to normal cell lines, Bonnet et al showed that DCA lowers apoptosis resistance in several human cancer cell lines (A549, MCF7, and M059K) through lowering mitochondrial membrane potential. It also increases mitochondria-derived hydrogen peroxide, increases potassium (K+) channel Kv1.5 efflux of K+, and lowers cytoplasmic calcium ions. In addition, they showed that oral DCA administration reduces tumor proliferation in athymic nude rats. Similarly, others have shown that DCA induces apoptosis of prostate cancer cell lines and also modulates antiapoptotic genes: BCL-29 increases caspases 3 and 9 expression,10 and increases p53 (antisuppressor gene) in endometrial cancer cell lines.11 However, it has been found that DCA concentration-induced cytotoxic effect varies between cancer cell lines. Some cell lines were resistant to DCA,11 and others need concentrations above 25 mM to induce a significant effect.12 Moreover, other studies showed that DCA reduced apoptosis under hypoxic conditions in some colorectal cancer cell lines,13 increased tumor volume in colorectal cancer xenograft mice,14 and at 25 mg/kg/day caused peripheral neuropathy in a clinical trial.14 However, the latter adverse event was not observed in patients who had received DCA at 12.5 mg/kg every 12 hours for 9–16 years.15

Cytokine modulation is a key factor in the progression or suppression of cancer within its microenvironment.16,17 Generally, activation of macrophages and/or dendritic cells results in the local production of cytokines, such as interleukin (IL)-12, which in turn amplify the innate immune response and stimulate T-cell function. Production of IL-12 is a major inducer of T helper 1 (Th1) and natural killer (NK) lymphocytes and their cytokines. These produced cytokines polarize macrophages, enhance dendritic cell maturation, and lower regulatory T-cell function by inhibiting regulatory cytokines such as transforming growth factor (TGF)-β and IL-10.16–19 Since it has been shown that DCA inhibits PDK and facilitates signaling pathways that lead to the inhibition of transcription factor nuclear factor of activated T-cells, we were encouraged to study DCA immunomodulatory activity. The present study was first based on whether DCA antiproliferative activity and cytotoxicity on 3-methylcholanthrene (MCA) fibrosarcoma could be enhanced in the presence of immune cells, and then determining if this phenomenon is related to DCA’s ability to modulate cytokines in vitro and in vivo. The long-term goal, however, is to understand DCA mechanisms in cancer therapy to develop protocols for its use in cancer treatment.

Materials and methods

Materials

Rosewell Park Memorial Institute (RPMI)-1640, fetal bovine serum, penicillin/streptomycin, amphotericin B (supplemented) (s)-RPMI and trypsin were obtained from (Merck Millipore, Billerica, MA, USA). DCA, MCA 98%, Igepal CA-630, phospholipid myristate 13-acetate (PMA), and phytohemagglutinin (PHA) were purchased from Sigma–Aldrich (St Louis, MO, USA). Endotoxin-free Dulbecco’s phosphate buffered saline (PBS) without calcium and magnesium was purchased from EuroClone SpA (Milan, Italy). Tissue culture flasks (25 cm² and 75 cm²) were obtained from Guangzhou Jet Bio-Filtration Products (Guangzhou, People’s Republic of China), and tissue culture and Maxisorb 96-well flat plates were products of Nalge Nunc International (Rochester, NY, USA). The kit for mouse erythrocytes lysis and the MagCellect mouse NK Cell isolation products of R&D Systems (Minneapolis, MN, USA). The 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reagent and sodium dodecyl sulfate were purchased from Trevigen (Gaithersburg, MD, USA). A rat monoclonal anti-mouse IL-12 p70 (immunoglobulin G1) was acquired from R&D Systems.

Animals

BALB/c male and female mice were utilized throughout the experiments as indicated. Mice were purchased from Yarmouk University (Irbid, Jordan) and were housed at the University of Petra animal facility in Amman. All mice were housed in a pathogen-free environment at 22°C with 12 hours light/dark cycle and with food and tap water ad libitum. All animal experiments were performed in compliance with the guidelines set by the Federation of European Laboratory Animal Science Association, and the study protocol was approved by the Deanship of Scientific Research at the University of Petra.

MCA-induced tumors and cell culture

MCA fibrosarcoma was induced in mice as described elsewhere.18,19 When the tumor size reached 1–2 cm in diameter, it was removed aseptically, cut in small pieces, minced, cultured in a T75 flask with FBS, and incubated at 37°C in a humidified chamber with 5% carbon dioxide (CO₂).
Culture medium was changed every 2 days, and cells were split when they reached confluence.

Spleen, macrophage, T-cell, and NK cell isolation
Mice were sacrificed by cervical dislocation. Spleen tissues were collected, squeezed between two slides to generate a single cell suspension, and red blood cells were lysed using M-lyse buffer (R&D Systems). The cells were washed with washing buffer, centrifuged for 10 minutes, and the supernatant was discarded. Cells were then counted and added to a 96-well plate at a density of 10^5 cells/100 µL/well and incubated at 37°C with 5% CO₂ in a humidified chamber.

The isolation of macrophages was performed according to the protocol described by Wahl and Smith. A volume of 15 mL from the above prepared spleen cell suspension was added to a 75 cm² tissue culture flask and incubated for 1 hour at 37°C with 5% CO₂ in a humidified chamber. The supernatant was then decanted, and the flask was washed twice with 10 mL FBS medium to remove nonadherent cells. The adherent macrophage cells were collected by scraping, and they were resuspended in s-RPMI and counted for further applications.

The isolation of NK cells and CD3+ T-cell isolation procedures were performed according to the manufacturer’s instructions. Isolated NK cells and CD3+ T-cells were counted, diluted to the proper concentration, and added to the 96-well culture plate.

Cell viability and proliferation assay
Cell viability and proliferation was assessed by MTT assay. Two hours or 24 hours after culturing spleen or MCA fibrosarcoma, respectively, 100 µL of DCA was added to each well and incubated for 48 hours. Following this incubation period, 20 µL MTT reagent was added and formed a purple precipitate. Four hours later 50 µL sodium dodecyl sulfate was added. When spleen was cocultured with the adherent MCA fibrosarcoma, and before adding the MTT reagent, the supernatant content of each well was carefully removed, leaving the adherent MCA-fibrosarcoma in the wells. Absorbance was read at 570 nm by GloMax®-Multi Detection System (Promega, Madison, WI, USA).

Cell culture for cytokine analysis
Spleen cells, macrophages, NK cells, or T-cells from healthy mice were treated as above and incubated with DCA. In the case of MCA fibrosarcoma stimulation, MCA fibrosarcoma cells were seeded into 96-well plates at a density of 10^5 cells/well for 24 hours, followed by the addition of spleen cells at a similar density. DCA was then added, and cells were incubated for an additional 48 hours. While in PMA-stimulation, spleen cells were seeded into 96-well plates at a density of 10^5 cells/well. After 2 hours, 50 ng/mL PMA was added, followed by the addition of 100 µL DCA for another 48 hours. Following the second incubation, the content of the wells was harvested and added to individual tubes containing 50 µL of 0.1% Igepal nonionic detergent diluted in endotoxin-free PBS for 10 minutes at 4°C. The tubes were stored at −30°C for cytokine analysis.

Cytokine analysis
Interferon (IFN)-γ, IL-17, IL-12, TGF-β, or IL-10 levels were assayed using enzyme-linked immunosorbent assay according to the manufacturer’s instructions (mouse Duoset® cytokines; R&D Systems).

Inflammation and histology assessment
Mice weighing 25–30 g were shaved in the dorsal area and left for 3 days, followed by a topical treatment with PMA (2.5 µg) in 200 µL acetone. DCA (20 mg/kg) was given orally to one of the PMA-treated groups on the day of application, and another two doses were given after 24 and 48 hours. Mice were sacrificed 48 hours after PMA application, and the skin from shaved areas was removed from each mouse. One skin sample was placed in 10% formalin for further histology examination, and the skin tissues from the other mice were weighed and transferred to 2 mL cold, sterile PBS containing 0.1% Igepal and incubated for 10 minutes. The skin was homogenized, centrifuged, and the supernatant was collected and stored at −25°C for cytokine analysis. Histopathology was performed by a certified histopathologist at Sultan Medical Lab, Amman, Jordan. Tissue sections were 7–9 µm thick and stained using hematoxylin and eosin stain.

Data analysis
Data in the figures are presented as mean ± standard error of the mean and assessed by using one way ANOVA analysis followed by a Tukey’s test (95% confidence) for multiple comparisons (SPSS version 17; IBM Corporation, Armonk, NY, USA). The 50% inhibitory concentration (IC₅₀) was calculated from each independent experiment, and the average ± standard error is presented. P<0.05 was considered statistically significant.

Results
High concentrations of DCA reduced the viability and proliferation of splenocytes
Using cell viability and proliferation assay, DCA reduced the viability and proliferation of unstimulated and
PHA-stimulated splenocytes, respectively, in a dose-dependent manner. This reduction was observed at high DCA concentrations (50 mM and 100 mM; \( P<0.01 \)) (Figure 1). However, the IC\(_{50}\) of DCA was 89±10 mM and 48±5 mM on unstimulated and PHA-stimulated splenocytes, respectively, indicating higher effect of DCA on splenocyte proliferation.

**DCA decreased MCA fibrosarcoma survival, and this activity was enhanced by splenocytes**

The first question was whether DCA can reduce MCA fibrosarcoma proliferation and viability and secondly, if such activity can be enhanced by splenocytes. Increasing concentrations of DCA significantly decreased the percent survival of MCA fibrosarcoma cells. The percent survival reached 13% and 16% at 50 mM and 100 mM DCA, respectively (\( P<0.001 \)) (Figure 2). The IC\(_{50}\) of DCA on MCA fibrosarcoma was 23.0±4.0 mM. However, when splenocytes were cocultured with MCA fibrosarcoma cells, the percent survival of MCA fibrosarcoma cells was reduced by 13% and shifted the DCA-induced survival curve to the left. After normalizing the effect of splenocytes, DCA at 10 mM significantly reduced the percent survival in comparison to the cultures without splenocytes (\( P<0.001 \)) (Figure 2). In addition, the IC\(_{50}\) of DCA dropped to 15.7±2.1 mM in comparison to 23.0±4.0 mM (\( P<0.05 \)) when MCA fibrosarcoma cells were cultured without splenocytes.

**DCA increased IFN-\( \gamma \) but not IL-17 production from stimulated and unstimulated splenocytes**

The following sets of experiments were performed to assess the association of DCA in cytokine modulation. First, we evaluated IFN-\( \gamma \) and IL-17 production using MCA-stimulated splenocytes to resemble the behavior of immune cells in vivo when they are in close proximity with cancer cells. In addition, we used a protein kinase C activator, PMA, as another stimulatory model. In PMA and MCA fibrosarcoma-stimulated splenocytes, DCA at 50 mM increased IFN-\( \gamma \) but not IL-17 levels in comparison to stimulated control cells (\( P<0.01 \)) (Figure 3A–D). Second, we examined whether DCA could induce such cytokines without exogenous stimuli. Herein, DCA was found to induce IFN-\( \gamma \) from unstimulated spleen cells in a concentration-dependent manner (Figure 3E), and the IFN-\( \gamma \) levels were significantly higher at 10 mM and 50 mM of DCA (\( P<0.05 \) and \( P<0.01 \), respectively).

**Notes:** Using MTT assay, DCA decreased the percent survival of MCA fibrosarcoma in a concentration-dependent manner. Adding spleen cells to MCA cells in a 1:1 ratio (\( 10^5 \) cells/well each) reduced MCA fibrosarcoma percent survival to 87% and shifted the DCA-induced survival curve to the left. After normalizing the effect of splenocytes, the percent survival of fibrosarcoma cells at 10 mM of DCA was significantly less than without spleen cells (\( P<0.001 \)). Data represent the average of percent survival of three to four independent experiments (±SEM), and each experiment consists of a minimum of six replicates per concentration.

**Abbreviations:** DCA, dichloroacetate; FS, fibrosarcoma; MCA, 3-methylcholanthrene; MTT, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide; Norm, normalized effects; SEM, standard error of the mean; Sp, splenocytes.
DCA increased IL-12 production from unstimulated macrophages but did not modulate IFN-γ production from T-cells or NK cells

To evaluate the cytokine modulatory effect of DCA on unstimulated purified subsets of immune cells, T-cells, NK cells, and macrophages were isolated from mouse spleen. DCA significantly increased the production of IL-12 from macrophages, and at a DCA concentration range of 10–100 mM, IL-12 production was significantly increased ($P<0.05$) (Figure 4A). On the other hand, DCA did not modulate IFN-γ production from NK cell or T-cell cultures (Figure 4B and C).

Anti-IL-12 antibody reversed DCA effect on IFN-γ production from splenocytes

To investigate if the DCA enhancing effect on IFN-γ production was due to induction of IL-12, anti-IL-12 antibody (160 ng/mL) was added to the cultures at the same time as the addition of DCA. The addition of anti-IL-12 antibody

---

**Figure 3** DCA increased IFN-γ but not IL-17 production from stimulated and unstimulated splenocytes.

**Notes:** DCA at 50 mM increased IFN-γ production from MCA fibrosarcoma-stimulated splenocytes ($^* P<0.05$ compared with its 0 counterpart) (A). DCA did not modulate IL-17 production from splenocytes stimulated with MCA fibrosarcoma cells (B). DCA at 50 mM increased IFN-γ production from PMA-stimulated splenocytes ($^* P<0.05$ when compared with its PMA counterpart) (C). DCA did not modulate IL-17 production from PMA-stimulated splenocytes (D). DCA at 10 mM and 50 mM increased IFN-γ production from healthy unstimulated splenocytes ($^* P<0.05$ and $^{**} P<0.01$, respectively, compared with its 0 counterpart) (E). Data represent the average of cytokine levels of three independent experiments (±SEM), and each experiment consisted of a minimum of six replicates per concentration.

**Abbreviations:** DCA, dichloroacetate; IFN, interferon; IL, interleukin; MCA, 3-methylcholanthrene; PMA, phorbol 12-myristate 13-acetate; SEM, standard error of the mean.
reversed the DCA enhancing effect on IFN-γ production. This reversal effect was complete at 10 mM DCA and up to 65% at DCA 50 mM ($P < 0.01$) (Figure 5).

**DCA restored IL-12, IFN-γ, and TGF-β levels and reduced IL-10 in PMA-induced skin inflammation in mice**

We generated PMA-induced skin inflammation in vivo to assess cytokine modulation following three oral administrations of DCA at 20 mg/kg. Applying PMA once topically induced severe skin inflammation in the deep dermis, reaching fatty tissue. The majority of cells in the affected area consists of neutrophils and macrophages (Figure 6A). The epidermis also showed pustules with areas of hyperkeratosis. In DCA-PMA treated mice, inflammation was still present in the dermis, and the epidermis showed large bullae filled with pustules consisting of neutrophils and macrophages. Such a histopathological pattern was investigated further by determining the type of cytokines produced and whether they reflected the infiltrating immune cells types. PMA lowered the levels of IL-12, IFN-γ, and IL-10 and increased TGF-β in the skin of mice 48 hours after PMA application ($P < 0.05$). However, oral administration of 20 mg DCA/kg reversed the effect of PMA on IL-12, IFN-γ, and TGF-β levels and decreased further IL-10 levels ($P < 0.05$) (Figure 6B–E).

**Discussion**

All previous studies confirmed that DCA can target cancer cells mainly via inhibiting PDK, followed by increasing cancer cell apoptosis. Similarly, the current study showed that DCA reduced the survival of MCA fibrosarcoma cells in a dose-dependent manner. However, the current study also showed that this survival reduction was enhanced when DCA is incubated with spleen cells. The latter suggests that DCA enhances killing of cancer cells through activating immune cells. In addition, although previous published work showed...
DCA restored IL-12, IFN-γ, and TGF-β levels and reduced IL-10 in PMA-induced skin inflammation in mice.

Notes: Images of mouse skin sections stained with hematoxylin and eosin stain (×10) show normal skin, acetone-treated skin, PMA-treated skin, and PMA-treated skin with three oral administrations of DCA (20 mg/kg) (A). PMA-induced severe inflammation with infiltration of mainly neutrophils and macrophages, and oral administration of DCA did not histologically modulate such an inflammatory pattern. DCA reversed the PMA effect on IFN-γ levels in skin after 48 hours of inducing the inflammation (*P<0.05 compared with the control counterpart) (B). DCA reversed PMA effect on IL-12 levels in skin after 48 hours of inducing the inflammation (*P<0.05 compared with the control counterpart) (C). DCA reversed the PMA effect on TGF-β levels in skin after 48 hours of inducing the inflammation (*P<0.05 compared with the control counterpart) (D). DCA significantly further reduced IL-10 levels when compared to PMA effect in skin after 48 hours of inducing the inflammation (*P<0.05; **P<0.01, respectively, compared with the control counterpart) (E). Data represent the average of cytokine levels (±SEM) of four mice per data point.

Figure 6: DCA restored IL-12, IFN-γ, and TGF-β levels and reduced IL-10 in PMA-induced skin inflammation in mice.
that DCA has no apparent toxicity by measuring hemoglobin, serum transaminases, and creatinine levels following 12-week oral administration of 50–100 mg/kg DCA; our data showed that high DCA concentrations (50–100 mM) reduced splenocytes viability and their proliferative ability. However, these latter concentrations are highly unlikely to be reached in vivo.

Recently, Ohashi et al have demonstrated that DCA promotes immunomodulatory activity. They have shown that DCA increases the number of IFN-γ producing CD8+ T and NK cells but did not significantly modulate IFN-γ levels from simulated splenocytes. However, looking carefully at their data, DCA exhibited a trend toward increasing IFN-γ production from nonlactic acid-treated stimulated splenocytes at the concentrations used (2–10 mM). In the present study, DCA increased the production of IFN-γ but not IL-17 from PMA and MCA fibrosarcoma-stimulated splenocytes. In addition, DCA increased the production of IFN-γ from unstimulated spleen cells. This increase, however, was not observed at 100 mM of DCA, which could be explained by the reduction of splenocytes survival at such concentration.

To look further into DCA immunomodulatory activity, DCA was tested on isolated immune cell subsets: macrophages, NK cells, and T-cells. DCA induced IL-12 production from unstimulated macrophages but not IFN-γ production from NK or T-cells. Moreover, when this IL-12 production is blocked, DCA enhancing IFN-γ production from nonlactate-treated stimulated splenocytes at the concentrations used. This increase, however, was not observed at 100 mM of DCA, which could be explained by the reduction of splenocytes survival at such concentration.

To investigate if DCA can modulate cytokines in vivo, a 12-week oral administration of 50–100 mg/kg DCA, our data showed that high DCA concentrations (50–100 mM) reduced splenocytes viability and their proliferative ability. However, these latter concentrations are highly unlikely to be reached in vivo.

In conclusion, our study showed that DCA modulates cytokines in favor of Th1 function, and this activation is associated with enhanced DCA cytotoxicity against MCA fibrosarcoma. Further studies are necessary to explain the action of DCA on macrophages and their polarization in the cancer microenvironment. Finally, DCA immunomodulatory effects are promising and merit further investigation to improve its use as an anticancer drug.
