In silico structure-based screening of versatile P-glycoprotein inhibitors using polynomial empirical scoring functions

Abstract: P-glycoprotein (P-gp) is an ATP (adenosine triphosphate)-binding cassette transporter that causes multidrug resistance of various chemotherapeutic substances by active efflux from mammalian cells. P-gp plays a pivotal role in limiting drug absorption and distribution in different organs, including the intestines and brain. Thus, the prediction of P-gp–drug interactions is of vital importance in assessing drug pharmacokinetic and pharmacodynamic properties. To find the strongest P-gp blockers, we performed an in silico structure-based screening of P-gp inhibitor library (1,300 molecules) by the gradient optimization method, using polynomial empirical scoring (POLSCORE) functions. We report a strong correlation ($r^2=0.80$, $F=16.27$, $n=6$, $P<0.0157$) of inhibition constants ($K_i_{\text{exp}}$ or $pK_i_{\text{exp}}$; experimental $K_i$ or negative decimal logarithm of $K_i_{\text{exp}}$) converted from experimental $IC_{50}$ (half maximal inhibitory concentration) values with POLSCORE-predicted constants ($K_i_{\text{POLSCORE}}$ or $pK_i_{\text{POLSCORE}}$), using a linear regression fitting technique. The hydrophobic interactions between P-gp and selected drug substances were detected as the main forces responsible for the inhibition effect. The results showed that this scoring technique might be useful in the virtual screening and filtering of databases of drug-like compounds at the early stage of drug development processes.

Keywords: ATP-binding cassette transporter, P-gp inhibitors, multidrug resistance, molecular docking, POLSCORE

Introduction

P-glycoprotein (P-gp) is a member of the ATP (adenosine triphosphate)-binding cassette multidrug transporter superfamily. It mediates the removal of xenobiotic agents from living cells by a P-gp-mediated efflux mechanism, a major cause of multidrug resistance (MDR). P-gp plays an important role in limiting drug absorption and distribution in different organs, including the intestines and the brain (blood–brain barrier), where it is extensively distributed and expressed. P-gp is a 170 kDa transmembrane protein, which includes cytosolic nucleotide-binding domain together with N-terminal and C-terminal halves. Each half in turn is comprised of membrane spanning and transmembrane domains.

P-gp inhibitors are mainly weakly amphiphilic or hydrophobic substances such as chemotherapeutics, steroid hormones, different antibiotics, and anti-HIV (anti-human immunodeficiency virus) protease inhibitors. Since P-gp can affect the pharmacokinetics and pharmacodynamics of its substrates, increasing attempts were being made to search for potential P-gp inhibitors at the early stage of drug discovery and development processes.

A number of in vitro assays for P-gp-oriented drug screening, such as cell-based transwell transport, radioactivity-labeled ligand binding, and drug permeability,
have been largely utilized to identify the potential P-gp inhibitor candidates\textsuperscript{10} and assess P-gp–drug interactions.\textsuperscript{11} However, due to their expense and time, the in vitro methods are not entirely suitable for the screening of large databases of drug-like chemical compounds. Primarily, these methods are usually used at the later stages of drug development processes, after the thorough structure-based virtual screening of extensive databases of bioactive, drug-like, small molecules. Therefore, in silico screening, based on different algorithms implemented for molecular docking, to predict P-gp inhibitors has paved the road to a rational drug design and screening process.\textsuperscript{12–14} On the other hand, to harness the discovery of the strongest P-gp blockers, high-resolution, crystallographic molecular structures of P-gp would improve a molecular docking precision for in silico prediction models.

Although a variety of molecular docking models for P-gp inhibitors have been successfully used for prediction of receptor–ligand interactions,\textsuperscript{14–16} there is no general scoring function regarding the filtration and selection of the best hits. The empirical scoring functions, such as those used in AutoDock\textsuperscript{17} (Scripps Research Institute, San Diego, CA, USA), AutoDock Vina\textsuperscript{18} (Scripps Research Institute), and others are most widely applied to estimate the Gibbs free energy of binding (ΔG).\textsuperscript{19–21} They are based on the counting of the number of hydrophobic and hydrophilic contacts and H-bonds between the P-gp receptor and its ligand.\textsuperscript{22} Therefore, to find the strongest P-gp blockers, we performed in silico structure-based screening of a P-gp inhibitor database via gradient optimization method, using the appropriate scoring techniques of AutoDock Vina and polynomial empirical scoring (POLSCORE) functions to calculate binding affinities and to correlate them to the experimentally determined half maximal inhibitory concentration (IC\textsubscript{50}) values.

### Computational methods

The electron diffraction of murine P-gp as a holo-structure (3G60) at 3.8 Å resolution with a cyclic-tris-(R)-valineselenazole (QZ59-RRR) ligand\textsuperscript{8} was retrieved from the Protein Data Bank as a PDB file. The P-gp molecule was processed for the ligand extraction and subjected to the initial molecular dynamics refinement by using the FG-MD (Fragment-Guided Molecular Dynamics) server.\textsuperscript{23} The VADAR (Volume, Area, and Dihedral Angle Reporter) server\textsuperscript{24} was implemented for stereochemical validation of the P-gp molecule to investigate the φ-ψ dihedral angles in a Ramachandran plot. Altogether, observed statistics showed that 70% and 23% of all residues were in core and allowed regions before, 82% and 12% after the molecular dynamics refinement. The expected values for the comparison were 90% and 7%, respectively, for the same regions obtained elsewhere, from the literature.\textsuperscript{25,26}

The P-gp inhibitor database included 1,300 molecules, which were assembled by the ADME (absorption, distribution, metabolism, and excretion) research team from the Functional Nano and Soft Materials Laboratory (FUNSOM, Suzhou, People’s Republic of China) and distributed through the scientific community for virtual screening and analysis.\textsuperscript{27}

Prior to the virtual screening procedure, PyRx software (Scripps Research Institute)\textsuperscript{28} was used to optimize the dataset. Gasteiger charges were added, and polar hydrogen atoms were assigned. The rotatable bonds were set up, and SDFs (structure-data files) were converted into PDBQT (Protein Data Bank, Partial Charge [Q], and Atom Type [T]) format.

The QZ59-RRR-associated binding site was reconstructed as a visual representation of the solvent-excluded molecular surface, known as the Connolly surface,\textsuperscript{29,30} by MOE 2009.10 (Chemical Computing Group, Montreal, Canada) modeling software. The solid molecular surface was generated with 1.4 Å of probe sphere radius and within 4.5 Å from the ligand atoms (Figure 1).

Rigid-flexible molecular docking was applied to the center of the QZ59-RRR-associated binding cavity with the AutoDock Vina docking engine,\textsuperscript{18} adopted for a structure-based virtual screening via the iDOCK (Department of Computer Science and Engineering, Chinese University of Hong Kong, Hong Kong) modification,\textsuperscript{31} using the following Cartesian coordinates: x = 19.11 Å, y = 52.37 Å, and z = −0.30 Å. The docking grid with a dimension size of 30 Å × 30 Å × 30 Å was used in the study. The AutoDock Vina output results

![Figure 1 QZ59-RRR-associated binding pocket in the crystalline structure of murine P-glycoprotein. The shown molecular surface is color-coded as follows: H-bonding areas are white; and hydrophobic and mild polar areas are colored in green and red, respectively. Hydrogen atoms are omitted for clarity.](https://www.dovepress.com/)

**Abbreviation:** QZ59-RRR, cyclic-tris-(R)-valineselenazole.
represented the docking scores as $\Delta G$ values. They were further converted to the predicted inhibition constants ($K_{\text{p}}$). The $K_{\text{p}}$ values for analyzed docking poses were calculated from the $\Delta G$ parameters as follows:

$$\Delta G = RT\ln(K_{\text{p}}),$$  \hspace{1cm} [1]

$$K_{\text{p}} = e^{\frac{\Delta G}{RT}},$$  \hspace{1cm} [2]

where $R$ (gas constant) is 1.98 cal*(mol*K)$^{-1}$, and $T$ (room temperature) is 298.15 Kelvin.

The $\Delta G_1$--$\Delta G_3$ binding affinity predictions were made for a human homology model, a mouse 3G60 model, and a mouse 3G61 model of P-gp using the same docking method and support vector machine algorithm integrated into the Althotas virtual laboratory webserver (Virtua Drug Ltd, Budapest, Hungary). The affinities were further converted in a similar fashion to their corresponding inhibition constants ($K_i [pK_i] - K_i [pK_i]$).

The docked conformations were ranked using the POLSCORE algorithm based on 25 POLSCORE functions to evaluate binding affinity from the P-gp–ligand complexes by calculated $pK_i$ values ($pK_i^{\text{POLSCORE}}$). The thorough scoring calibration has been previously performed to use geometric parameters, calculated from the atomic coordinates, to evaluate the experimental $pK_d$ ($pK_i$) values as closely as possible to a training set composed of hundreds of co-crystallized protein–ligand complexes. The weights obtained from this training set were used to build appropriate POLSCORE functions.

The $IC_{50}$-to-$K_i$ converter was used to compute $K_i$ values from experimentally determined $IC_{50}$ values for inhibitors of proteins and enzymes that obey classic Michaelis-Menten kinetics of protein–ligand interactions. The $IC_{50}$ values were obtained from the study of Keogh and Kunta as determined when investigating the inhibition of human P-gp transport of 30 nM [H]-digoxin. The $IC_{50}$ values were converted into the experimental inhibition constant values ($K_i^{\text{exp}}$ or $pK_i^{\text{exp}}$) according to the protein–ligand interaction equation for competitive species:

$$K_i^{\text{exp}} = \frac{IC_{50}}{L_{50} + P_0 + \frac{K_d}{K_d} + 1},$$  \hspace{1cm} [3]

where $P_0$ is free protein at 0% inhibition (positive control), $L_{50}$ is free ligand at 50% inhibition, $IC_{50}$ is free inhibitor at 50% inhibition, and $K_d$ is the dissociation constant. The default parameters for protein concentration ($P = 0.03 \mu M$) and dissociation constant ($K_d = 0.0179 \mu M$) were used. The ligand concentration ($L = 2.0 \mu M$) was specified according to the GF120918 compound’s ability to achieve the entire P-gp inhibition.

Molecular graphics and visualization were performed with the LigPlot+ program (EMBL-EBI, Wellcome Trust Genome Campus, Hinxton, UK) in order to build two-dimensional interaction diagrams from three-dimensional coordinates. Statistical analyses were performed using a linear regression analysis, followed by graphic representation using GraphPad Prism v.4 (GraphPad Software, San Diego, CA, USA).

**Results and discussion**

Our search for a strong inhibitor focused on an inhibitor that allows for better intestinal drug absorption and blood–brain barrier transfer after inhibition. We wanted to improve inhibitor selection by extensive in silico prescreening. For this, we considered the P-gp inhibitor dataset, including 1,300 molecules, among which 796 molecules (61.2%) were P-gp inhibitors, and 504 molecules (38.8%) were P-gp non-inhibitors (Supplementary material 1). The experimental data were retrieved and compiled from 104 pieces of published literature to increase the molecular diversity of the database. Data from Ramu and Ramu, 37,38 (347 molecules) and Bakken and Jurs (369 molecules) were important sources of the P-gp inhibitor dataset. The experimental ratio for MDR reversal agents was used as a determining parameter of whether a compound is an inhibitor. Since the holo-P-gp structure does not bind ligands, an inward-facing apo-P-gp conformation was chosen as a reliable drug-binding model. This conformation represents an initial stage of the transport cycle that is competent for inhibitor binding. Therefore, we screened the P-gp inhibitor database against the binding cycle associated with the removed QZ59-RRR ligand of murine P-gp protein by calculating the Gibbs free energy of binding. A standard rigid-flexible AutoDock Vina technique produced two main results: a particular conformational sampling as a docking pose of the ligand molecule within the binding site, and an affinity ($\Delta G$) describing the receptor–ligand interaction strength. All docking poses were ranked according to their $\Delta G$ values, which ranged from $-13.904$ to $-1.682$ kcal*mol$^{-1}$ (Supplementary material 2). To detect the false-positive docking results, we selected the top-ranked 120 compounds with minimal $\Delta G$ values, ranging from $-13.904$ to $-10.002$ kcal*mol$^{-1}$. Of these, 106 (88.3%) were P-gp inhibitors, with a mean value of $-10.62$ kcal*mol$^{-1}$ and a standard deviation of 0.57 kcal*mol$^{-1}$, and 14 molecules (11.7%) were P-gp non-inhibitors, with a mean value of $-10.74$ kcal*mol$^{-1}$ and a standard deviation of 0.96 kcal*mol$^{-1}$ (Figure 2A). To detect the false-negative docking results, we selected the bottom-ranked
150 compounds with maximal $\Delta G$ values from $-6.998$ to $-1.682$ kcal*mol$^{-1}$. Of these, 40 (26.7%) were P-gp inhibitors, with a mean value of $-6.58$ kcal*mol$^{-1}$ and a standard deviation of $0.37$ kcal*mol$^{-1}$, and 110 molecules (73.3%) were P-gp non-inhibitors, with a mean value of $-6.28$ kcal*mol$^{-1}$ and a standard deviation of $0.77$ kcal*mol$^{-1}$ (Figure 2B). These results indicated that in almost 90% of top-ranked compounds, virtual screening worked better at predicting the P-gp inhibitory potencies than separating non-inhibitors for bottom-ranked molecules (substances with high $\Delta G$ values), which might be P-gp substrates with a propensity to attach to the P-gp binding cavity. In addition, the area under the receiver operating characteristic curve (AUC) was also examined since the true positive and the true negative are known in this study. 40 The result showed a good performance for the AutoDock Vina docking run, with an AUC value of 0.62 and a standard error of 0.048 ($P<0.032$); while a random selection performance presented with a 0.5 AUC value (Figure 3).

The P-gp inhibitor D559 and polypeptide antibiotic actinomycin D were associated with the best binding modes, which represent the minimal $\Delta G$ values: $-13.904$ and $-13.126$ kcal*mol$^{-1}$ ($-9.1$ kcal*mol$^{-1}$ for QZ59-RRR) because of the strong binding affinity and intermolecular forces between P-gp receptor and its inhibitor. The D559 compound was evaluated as a P-gp inhibitor in the database via experimental data mining, while actinomycin D was not. 27 However, actinomycin D was previously determined as a P-gp substrate, and its P-gp-mediated efflux was substantially inhibited in MDR cells by the monoclonal antibody (UIC2 clone) against the extracellular epitope of P-gp. 41 Moreover, this polypeptide antibiotic might also bind at high capacity to the P-gp molecule due to its enhanced active efflux mechanism observed with adriamycin as part of a functioning MDR for these different classes of drugs. 42

In the next step, the docked conformations were further separated using POLSCORE to evaluate a ligand binding affinity from P-gp–ligand complexes by calculating the $pK_i$POLSCORE values for selected P-gp inhibitors ($n=6$). The experimental inhibitory potencies ($IC_{50}$ or $pIC_{50}$) of the inhibitors GF120918, itraconazole, ketoconazole, astemizole, quinidine, and verapamil were transformed into inhibition constants ($K_i_{exp}$ or $pK_i_{exp}$) for further comparison with predicted $pK_i$POLSCORE (Table 1) and other predicted $pK_i$ values, such as $pK_i_{pred}$, $pK_i_1$, $pK_i_2$, and $pK_i_3$ (Tables 2 and 3), calculated from appropriate $\Delta G$ parameters. However, the $K_i_{exp}$ calculation

derived from Equation 3 has taken into consideration that the range of inhibitor potencies resolved in fluorescence polarization-based binding assay is limited by the affinity of the fluorescent ligand. In other words, as the Kd value of the fluorescent ligand decreases, the range of resolvable inhibitor potency increases. Therefore, it is not feasible with this method to correctly determine Ki values for inhibitors with binding affinities higher than the fluorescent ligand because of the assay constraint.83

Using a linear regression fitting technique, a strong correlation was observed for our predicted values and experimental results: \( r^2 = 0.89, F = 32.67, P < 0.0046 \) for pKi_\text{exp}; \( r^2 = 0.80, F = 16.27, P < 0.0157 \) for pKi_{POLSCORE}; \( r^2 = 0.79, F = 14.99, P < 0.0175 \) for pKi_2 (mouse 3G60 model); and \( r^2 = 0.76, F = 12.54, P < 0.0240 \) for pKi_1 (mouse 3G61 model) (Figure 4A–E). However, the true pKi_{POLSCORE} values lie within predictive range closer to the pKi_\text{exp} determinants, at least for some of the compounds, such as GF120918 (9.09 and 9.0), itraconazole (7.92 and 8.10), and astemizole (8.09 and 7.96).

On the other hand, the pKi_1 value, predicted for the human homology P-gp model, was shown to correlate poorly with experimental inhibition constants \( r^2 = 0.51, F = 4.17, P < 0.1107 \) (Figure 4C). This low correlation might be explained primarily by the use of the human P-gp homology model as a receptor molecule with a substantial difference in the complex geometry of the binding cavity from the mouse structure. Regardless of a high amount of amino acid conservation between the human and murine P-gp structures, the deviations were established with 13% of sequence identity within the P-gp binding cavity.84 Interestingly, pKi_1 showed better correlating strength than pKi_2 because of the better 3G60 model optimization used in structure-based virtual screening.

The binding modes for the selected P-gp inhibitors are shown in Figure 5 as two-dimensional schematic diagrams as they revealed very clear ligand occupancies within the P-gp binding pocket. As all of the inhibitors occupy the binding site well, the majority of the contacts between the P-gp binding site and selected substances are nonpolar, making use of the hydrophobic protein residues in the binding pocket. Aller et al.3 mentioned the fact that certain amino acid residues contact cyclic hexapeptide inhibitors, but the functional role of these residues in binding to each inhibitor is different. As expected, all analyzed ligands utilized different binding modes with different amino acid residues involved due to structural and conformational mismatches. The active site associated with the QZ59-RRR ligand is composed of amino acid residues, such as Met88, Phe332, Ile338, Phe338, Gln721, Tyr949, Phe724, Phe974, Val978, Tyr303, Phe728, Ser975, and Leu335. As most of the amino acid residues in the P-gp active site are hydrophobic, they are, therefore, involved in strong hydrophobic interactions with the co-crystallized QZ59-RRR ligand.

To find the similarities in binding modes for selected P-gp inhibitors and the QZ59-RRR ligand, we tried to find common amino acid residues involved in hydrophobic interactions. Taken together, we found that quinidine and verapamil interact with the P-gp protein in a similar fashion, indicating protein residues that are in common to those associated with the cyclic hexapeptide inhibitor used as a reference molecule (Figure 5E and F). These ligands may occupy very similar and overlapping binding regions, while the rest of the ligands bind to different regions within the QZ59-RRR-associated binding site.

Interestingly, both important Phe724 and Val978 residues are present in the interaction. It has been previously shown that these residues in mice and Phe728/Val982 in humans are playing pivotal roles in P-gp protection from MTS (methanethiosulfonate) labeling by verapamil, indicating their importance for drug binding.\(^{44,45}\)

Additionally, due to the hydrophobic effect, the number of aromatic rings in selected molecules might also play a role in establishing the $\pi-\pi$ stacking interactions between them and aromatic residues of P-gp. In this regard, the GF120918 compound is composed of a maximal number of aromatic rings (four) to be driven by a significant contribution from stacking interactions between its rings and the aromatic bases of Phe299, 310, 766, and 833, and Tyr303 and 306 residues. The other molecules include three aromatic rings for itraconazole and astemizole, two rings for ketoconazole and verapamil, and one ring for quinidine. Hence, it can be concluded that the presence of aromatic rings involved in the $\pi-\pi$ stacking interactions is also important for the binding activity of the inhibitors.
Conclusion
In this current study, we report an extensive in silico structure-based screening of 1,300 different P-gp inhibitors by the gradient optimization method, using POLSCORE functions. On the basis of the large amount of data on versatile P-gp inhibitors, the filtering and ranking of chemical compounds was performed and examined systematically. The use of AutoDock Vina, together with POLSCORE, to estimate the pKi values for P-gp–inhibitor complexes was concomitant with experimentally determined affinities (IC_{50} or pIC_{50}) for GF120918, itraconazole, ketoconazole, astemizole, quinidine, and verapamil compounds. A strong correlation ($r^2=0.80$, $F=16.27$, $n=6$, $P<0.0157$) was observed for inhibition constants (Ki or pKi) calculated from experimental IC_{50} values and POLSCORE-predicted constants ($K_i_{POLSCORE}$ or pKi_{POLSCORE}) using a linear regression fitting technique. The hydrophobic forces involved in the interaction between the P-gp protein and analyzed molecules largely contributed to the inhibition effect. To our knowledge, this is the first attempt to filter and examine a large P-gp inhibitor database by gradient optimization docking algorithm combined with POLSCORE functions.
