Abstract: Degradation products of titanium implants include free ions, organo-metallic complexes, and particles, ranging from nano to macro sizes. The biological effects, especially of nanoparticles, is yet unknown. The main objective of this study was to develop Ti-protein antigens in physiological solutions that can be used in testing of cellular responses. For this purpose, 0.1% TiO₂ nanoparticles less than 100 nm were mixed with human serum albumin (HSA), 0.1% and 1%, in cell culture medium (DMEM, pH 7.2). The Ti concentrations in the resulting solutions were analyzed by inductively coupled plasma mass spectrometry. The stability of the nanoparticles in suspension was analyzed by UV -vis spectrophotometer and Dynamic Light Scattering. The concentration of Ti in suspension was dependent on the presence and concentration of HSA. Albumin prevented high aggregation rate of TiO₂ nanoparticles in cell culture medium. It is shown that nano TiO₂-protein stable aggregates can be produced under physiological conditions at high concentrations, and are candidates for use in cellular tests.

Keywords: titanium, nanoparticle, hypersensitivity to Ti

Introduction

Titanium (Ti) is widely used in medicine and dentistry, either in its pure form or in alloys, due to the combination of physical, chemical and biological properties (Scharnweber et al 2002). Titanium is employed in eg, joint prostheses, fracture fixation devices, endovascular stents, pacemaker enclosures, and dental materials (Peters et al 1984; Yamauchi et al 2000; Stoeckel et al 2004; Tschernitschek et al 2005).

The high corrosion resistance of Ti is due to a strongly passivating oxide layer (Hallab et al 2004). Nevertheless, Ti degrades under mechanical stress, abrasion, low pH and low oxygen level (Tschernitschek et al 2005). It is established that Ti-based implants release particles and ions to the surrounding tissue and fluids, as has been demonstrated with hip implants (Mckellop et al 1990; Brien et al 1992), as well as with miniplates used for jaw fractures (Schliephake et al 1993; Torgersen et al 1995), and even unloaded dental implants (Arys et al 1998; Flatebø et al 2006). However, the biological consequences of the degradation products, ions, nano- or micrometer sized particles, remain unclarified.

Based mostly on case reports, it has been suggested that hypersensitivity to Ti is associated with implant loosening (Wooley et al 1996; Matthew and Frame 1998), or skin reactions (Peters et al 1984; Yamauchi et al 2000; Tamai et al 2001; High et al 2006; Thomas et al 2006; Watanabe et al 2006). Diagnosis of contact allergy to metals usually relies on combination of anamnestic information and in vivo tests such as a epicutaneous patch test (Hallab et al 2001; Granchi et al 2006), and – in some instances – ex vivo tests such as a Lymphocyte Stimulation Test (LST) on cells from blood samples (Hallab et al 2001). Hypersensitivity tests have not been established for Ti (Lalor et al 1991; Hallab et al 2001; Klein et al 2004) and Ti is
Materials and methods

Materials

Commercially pure titanium dioxide (TiO2) nanoparticles, 99.9%, consisting of the crystallographic forms anatase and rutile (MW05084, Sigma-Aldrich, St. Louis, USA) were used. The powder particles have an average diameter <100 nm. The specific surface area of the TiO2 nanopowder, determined by the Brunauer-Emmet-Teller (BET) method according to the nitrogen adsorption (ASAP 2020 Volumetric Adsorption, Micromeritics), was 19.6 m²/g. The cell culture medium used was Dulbecco’s Modified Eagle’s Medium (DMEM, Sigma-Aldrich, D6046, UK). The medium is a high ionic strength solution and contains low amounts of glucose and amino acids. Commercially available human serum albumin (HSA) (96%–99%, Sigma-Aldrich, SL04521, St. Louis, USA) was used.

Methods

Preparation of potential antigens and determination of Ti-concentrations

Several suspensions were prepared by mixing the reagents in DMEM. A suspension was prepared by mixing 50 mg TiO2 in 50 ml DMEM for a concentration of 0.1% TiO2. Different quantities of HSA – 50 mg (0.1%) and 500 mg (1%) – were added. Control suspensions of 0.1% TiO2 nanoparticles in DMEM (0% HSA) were prepared. The suspensions were placed in a shaking machine in an incubator at 37 °C for 8 days in order to assess the effect of exposure time between nano-TiO2 and HSA. Aliquots of 2 ml were taken from each solution, after 1 h, 24 h, and 8 days. The samples were centrifuged at 3000 rpm (15 min), and sterile filtered (Millipore HV filters, Millipore, Carrigtwohill, Co. Cork, Ireland, pore size 0.45 μm). The assays ran 6 times.

The total concentration of titanium in the filtered suspensions was determined Inductively Coupled Plasma - Mass Spectrometry (ICP-MS). The instrument (Element 2, Thermo Finnigan, Bremen, Germany) used a high resolution, magnetic sector field. Colloidal suspensions of nanoparticles with average sizes of 400 nm have been shown to be totally ionized in the argon plasma, which holds a temperature of nearly 8000 K (Degueldre and Favarger 2003). The instrument was operated at medium resolution (R = 4000) for the isotopes Ti47 and Ti49, and the resulting signal count at the mass detector was calibrated to represent the total Ti-concentration in the sample. The sample aliquots (0.5 ml) were diluted by a factor of 100–200 with ultra-clean 1% nitric acid before measurements. An internal standard of indium (1 µg/l) was added to all the samples to monitor and to correct for any instrumental fluctuations. Calibration was performed by standard addition using calibrating solutions made from a 1000 mg/l stock standard solution (Merck, Darmstadt, Germany). The method detection limit for the Ti analysis was 0.56 µg/l. The accuracy of the analytical method was monitored by a reference material (Seronorm Trace Elements Serum level 1, lot MI0181, Sero AS, Billingstad, Norway) with a recommended Ti-value of 2.6 µg/l. We found a median value of 2.55 (n = 10).

Transmission electron microscopy (TEM)

Suspensions with 0.1% TiO2 nanoparticles in DMEM only and in DMEM + 0.1% HSA were prepared at the same conditions (shaking machine; incubator 37 °C) as previously mentioned. The suspensions were shaken for 4 days. The samples prepared for TEM images were not centrifuged and sterile filtered in order to visualize the TiO2 nanoparticles and aggregate formation. One drop (10 μl) from each suspension,
Formation of titanium antigens
diluted 10 times, was placed on a Cu mesh grid. The excess liquid was removed immediately by filter paper. The samples were lyophilized overnight at room temperature, and analyzed using a transmission electron microscope (JEM-1230) at electron emission of 60 kV.

Physicochemical characterization: Stability of TiO$_2$ nanoparticles in suspension

Dynamic light scattering (DLS) was used to measure the hydrodynamic diameter of aggregates in suspension. The particles in suspension are subject to the thermal Brownian motion and the rate of particles movement depends upon their size (Tkachenko et al 2006). Suspensions of 0.1% TiO$_2$ in DMEM and TiO$_2$ with 0.1% and 1% of HSA in DMEM were prepared, shaken for 2 hours, ultrasonicated for 30 sec, and analyzed. The measurements were conducted on the Zetasizer NS (Malvern Instruments Ltd, UK).

The TiO$_2$ nanoparticles sedimentation rate was determined by monitoring the absorbance at 337 nm (the wavelength of maximum absorbance of the solid) as a function of time by UV-vis spectrophotometer (Perkin-Elmer, Model 554, Germany). The TiO$_2$ suspensions were prepared in the same manner as described for DLS study and analyzed before and after sterile filtration (pore size 0.45 µm). All measurements were made at 25 °C. Square cuvettes with 1 cm light path were used. The center of the light beam passed through the cuvette 1.5 cm above its bottom.

Statistical analysis

Statistical analysis was performed using SPSS version 13.0. P-values less than or equal to 0.05 were considered significant. Friedman test was used for time-line differences and Mann-Whitney test for the two levels of albumin concentrations.

Results

The preparation of antigens in the first part of our study was proceeded for a period of 8 days, in orders to asses the effect of the exposure time between nano-TiO$_2$ and albumin on Ti concentration. Based on obtained results, the study continued with TEM imaging and the determination of stability of nano-TiO$_2$ antigens in suspension.

The filtered suspensions, with no HSA, gave a low median Ti concentration (by ICP-MS), below 1 µg/l, and unaffected by exposure time. The presence of HSA increased the concentration of Ti by 2–3 orders of magnitude when compared to controls (suspensions without HSA). Longer exposure time raised also the Ti concentrations in suspensions with 0.1 and 1% HSA (Figure 1). Differences between Ti concentrations with 0.1% HSA and 1% HSA were statistically different for all time points, except at day 8.

The TEM images of the unfiltered suspensions revealed that the individual TiO$_2$ nanoparticles were spherical, with diameters ranging from 20 to more than 100 nm. The TiO$_2$ nanoparticles formed typical aggregates in both suspensions, with and without albumin (Figures 2a and 2b).

The DLS measurements results showed that TiO$_2$ nanoparticles formed large aggregates in DMEM without HSA, but the mean aggregate size was about 1/5 in presence of HSA. After filtration, the mean aggregate size was about half of the unfiltered suspensions (Table 1). The evolution of TiO$_2$ aggregates size in DMEM with 1% HSA revealed a slow growth over 20 h period (regression model: mean size (nm) = 1.46 time (h) + 210; $R^2 = 0.83$).

The sedimentation rate results revealed that the TiO$_2$ aggregates sedimented rapidly (5 h) in absence of HSA, whereas in presence of HSA, the sedimentation rate was close to zero (Figure 3). After filtration, the TiO$_2$ aggregates were stable in suspension all along a 20 h period (Figure 3). In DMEM without HSA, after filtration, the TiO$_2$ nanoparticles were not detectable by either Zetasizer or the UV-vis spectrophotometer.

Discussion

The results presented in this study show that the combination of human serum albumin and Ti in the form of nanoparticles raises the bioavailability of Ti in suspension, most likely through a metal-protein association.
Using nanoparticles to develop a potential diagnostic reagent for hypersensitivity testing is new and clinically appropriate because nanometer sized wear products have been found in tissues surrounding implants (Buscher et al 2005). Titanium dioxide nanoparticles have greater potential toxic effect on cells than the conventional size particles (Chen et al 2006; Long et al 2006).

When compared with the micrometer-sized and easily detectable particles, the nanoparticles have larger specific surfaces and different physiochemical properties, which mean higher surface energy (Long et al 2006). Consequently, their interaction with cell membrane, cell structure, or cell activity may differ from the larger-size particulate matter (Long et al 2006).

Our results suggest that TiO2 nanoparticles, which aggregate and sediment rapidly in cell culture medium, are more stable in suspensions when they are in presence of HSA. This increased stability could be due to protein adsorption onto the surface of TiO2 nanoparticles or aggregates (Klinger et al 1997; Oliva et al 2003). Moreover, steric repulsive forces caused by the protein chain reduce the net attractive interactions between particles, and thus alter the aggregation rate (Tirado-Miranda et al 2003; Limbach et al 2005). The presence of albumin slowed down the aggregate settling as shown by the sedimentation rate test, and raised the Ti concentration orders of magnitude even after filtration.

In presence of HSA, the mean aggregate size, as revealed by DLS, was slightly smaller than the pore size of 450 nm and thus most of the aggregates passed through the filter membrane (Table 1). These results are in concordance with results from the quantitative chemical analyses (ICP-MS) showing high final Ti concentration in the samples (Figure 1). Furthermore, the effect of HSA on the reducing the aggregate size of TiO2 nanoparticles in suspensions is supported by our sedimentation study (Figure 3). Ultrasonication used for 30 sec of TiO2-albumin suspensions showed also an effect on clustering size, by breaking down the big aggregates.

Few studies have been done on the colloidal stability of nanoparticles in cell culture media. Our results are in accordance with Long et al (2006) who revealed that DMEM affects the rate of aggregation and consequently the size of clusters. In solution with high ionic strength without proteins, such as DMEM medium, the rate of aggregation is high, leading to

| Table 1 Mean hydrodynamic diameter for TiO2 after 2 h of shaking (n = 3) |
|-----------------|-----------------|-----------------|-----------------|
| Sample          | Mean hydrodynamic diameter (nm) ± SD |
|                 | Before filtration | After filtration |
| TiO2/DMEM       | 2765 ± 124       | Not detected    |
| TiO2 + 0.1%     | 446 ± 26         | 215 ± 1.7       |
| HSA/DMEM        |                  |                 |
| TiO2 + 1%       | 430 ± 23         | 216 ± 1         |
| HSA/DMEM        |                  |                 |
fast sedimentation (Gomez-Lopera et al 2006; Phenrat et al 2007). However, if HSA is present, the adsorption of the protein onto TiO$_2$ surfaces is almost independent of the ionic strength (Oliva et al 2003). The binding mechanisms of the TiO$_2$-albumin interaction need more research.

It can be assumed that the TiO$_2$ nanoparticles behave in a similar manner in vivo, making aggregates and binding to proteins. This supports the idea that the metal released by implant degradation does not exist as unbound ionic or colloidal forms in serum but bound to serum proteins (Hallab et al 2000).

Since our potential antigens could be prepared already after 2 h of shaking, we recommend using these fresh suspensions, in hypersensitivity testing, instead of those mixed for 8 days.

The biological reactivity of the new possible antigens is now being pursued in Lymphocyte Stimulation Test (LST). More tests needs to be done in order to standardize the method.

**Conclusions**

The TiO$_2$ nanoparticle-albumin antigen could be clinically relevant as it mimics degradation products of Ti-based implants. Albumin has an important role in the colloidal stability of TiO$_2$ nanoparticles in suspension, and thus, on the bioavailability of Ti for cellular tests. The applicability of the substances in clinical testing of hypersensitivity has to be elucidated.
