**Abstract:** New approaches to the treatment of multidrug-resistant and extensively drug-resistant tuberculosis (TB) are badly needed. Not only is the success rate of current treatment regimens suboptimal but existing regimens require multiple drugs and lengthy courses and may lead to significant toxicities. The treatment landscape is beginning to shift, however, with the recent approvals of the new TB drugs bedaquiline and delamanid. Delamanid, a dihydro-imidazooxazole, has been shown to have excellent activity against *Mycobacterium tuberculosis* in both in vitro and in murine TB models. It has also recently been reported to improve rates of sputum culture conversion in patients with multidrug-resistant TB when added to an optimized background regimen. Although generally well tolerated, delamanid has been associated with QT prolongation, which may be of particular clinical concern when paired with other TB drugs that may also have this effect, most notably the fluoroquinolones. Ongoing studies will help to clarify delamanid's role in the treatment of drug-resistant TB.

**Keywords:** delamanid, OPC-67683, Deltyba, tuberculosis

## Introduction

Although shorter, better-tolerated treatment regimens would be valuable for drug-susceptible tuberculosis (TB), the need is even more acute for multidrug-resistant (MDR) and extensively drug-resistant (XDR) TB. Cases of MDR TB are resistant to the front-line drugs isoniazid and rifampicin, whereas cases of XDR TB are additionally resistant to a fluoroquinolone and at least one of the injectable anti-TB drugs such as kanamycin, amikacin, or capreomycin.<sup>1</sup> By World Health Organization estimates, approximately 480,000 persons developed MDR TB in 2013, with 210,000 deaths from MDR TB occurring that year.<sup>2</sup>

Current treatment regimens for MDR and XDR TB are toxic, lengthy, and generally associated with low rates of clinical success.<sup>3</sup> Encouragingly, the treatment outlook is improving, as witnessed by the recent approvals of bedaquiline and delamanid and multiple other agents under investigation.<sup>4,5</sup> In this review, we will summarize existing data for delamanid, which was granted conditional marketing approval by the European Medicines Agency in 2014. We highlight areas where questions remain concerning delamanid's pharmacology, safety, and/or efficacy.

## Mechanism of action

Delamanid ([2R]-2-methyl-6-nitro-2-[(4-{4-[4-(trifluoromethoxy)phenoxy]-1-piperidinyl}phenoxy)methyl]-2,3-dihydroimidazo[2,1-b][1,3]oxazole) is a dihydro-imidazooxazole previously known as OPC-67683 and is marketed under the trade name Deltyba™ by Otsuka Pharmaceutical Co., Ltd (Tokyo, Japan) (Figure 1). Delamanid's mechanism of action is incompletely understood but may involve inhibition of mycolic

acid synthesis, possibly via a radical intermediate. Studies in *Bacillus Calmette-Guérin* showed that delamanid inhibited production of both methoxymycolic acid and ketomycolic acid.<sup>6</sup> Like the related drug PA-824,<sup>7</sup> delamanid has been reported to have activity against both growing and nongrowing mycobacteria.<sup>8</sup> It is thought to be a prodrug, requiring activation by the mycobacterial F420 system, including the nitroreductase Rv3547.<sup>6,8</sup>

## In vitro activity

The reported minimal inhibitory concentrations (MIC90) for delamanid range from 0.006  $\mu\text{g/mL}$  to 0.05  $\mu\text{g/mL}$  across *Mycobacterium tuberculosis* (Mtb) isolates, independent of strain resistance class (ie, pan-susceptible, MDR, or XDR strains).<sup>6,8,9</sup> Similar results were obtained in limited testing of other members of the Mtb complex, whereas MICs were more variable for nontuberculous mycobacteria.<sup>8</sup>

Delamanid's activity was also studied in a cell culture system to model its activity against intracellular Mtb. In pulse-dose experiments, delamanid exhibited similar killing to rifampin against intracellular Mtb.<sup>6</sup>

Additional studies evaluated delamanid's ability to kill drug-tolerant TB. Such phenotypic resistance is thought to represent a major barrier to treatment shortening in TB.<sup>10</sup> Using a liquid culture system, Saliu et al<sup>11</sup> found that delamanid at 1  $\mu\text{g/mL}$  showed a sterilizing effect similar to rifampin against the majority of a panel of drug-tolerant Ugandan Mtb isolates.

## Pharmacokinetics

Delamanid's water solubility is poor,<sup>11</sup> and its absorption is increased more than twofold by coadministration with food. Its absolute bioavailability is unknown but estimated to be between 25% and 47%. It is more than 99% protein bound, with a high volume of distribution ( $V_z/F$  of 2,100 L) and a half-life of 30–38 hours. Delamanid is excreted primarily in the stool, with less than 5% excretion in the urine. It is thought

to be primarily metabolized by albumin,<sup>8</sup> with secondary contributions from P450 enzymes, primarily CYP3A4. Four major metabolites (M1–M4) have been identified in plasma in patients receiving delamanid.<sup>12</sup> Although delamanid's metabolites have limited antimycobacterial activity, they may still contribute to QT prolongation, as discussed below.<sup>8,13</sup>

Based on toxicity in animal models, delamanid is not recommended to be used in pregnant women or women of childbearing age unless they are using contraceptives. Animal studies have also indicated that delamanid is excreted in breast milk, so it is not recommended for breastfeeding women.<sup>13</sup>

The dose of delamanid approved by the European Medicines Agency is 100 mg twice daily.<sup>13</sup> No dose adjustments are required for mild to moderate renal impairment, but there are no data to guide use in severe renal insufficiency. Delamanid may be used in mild hepatic impairment but is not recommended for moderate to severe hepatic impairment. A single case report describes a 12-year-old boy with XDR TB treated with delamanid, but otherwise there are no published data for delamanid's use in pediatric patients.<sup>14</sup> There are also currently no guidelines for dose adjustment in the elderly.<sup>13</sup>

## Delamanid resistance

Delamanid resistance is thought to arise from mutations in the mycobacterial F420 genes (*Rv3547*, *fgd*, *fbIA*, *fbIB*, *fbIC*) associated with the prodrug's activation. In the clinical studies described here, a threshold of 0.2  $\mu\text{g/mL}$  was used to define delamanid resistance; however, this cutoff requires further clinical validation. The spontaneous rate of delamanid resistance has been reported as  $6.44 \times 10^{-6}$ – $4.19 \times 10^{-5}$ , emphasizing the need to protect delamanid with other active anti-TB drugs during therapy.<sup>8</sup>

A delamanid and PA-824 cross-resistant Mtb isolate that was obtained prior to the clinical study of either drug has been reported,<sup>15</sup> although the molecular basis for resistance and treatment history of this isolate were not described.

Published clinical studies have not conducted baseline delamanid susceptibility testing of Mtb isolates, although efforts are being undertaken to collect these data where possible on banked isolates.<sup>8</sup>

## Drug–drug interactions

Available data suggest that delamanid does not have a significant effect on transporters such as P-glycoprotein.<sup>8</sup> Moreover, *in vitro* testing suggests that delamanid neither inhibits nor induces P450 enzyme at concentrations up to 100  $\mu$ M,<sup>6,12</sup> although the effects of higher concentrations (as might occur in the gut) have not been reported.<sup>8</sup> A recent report suggests that delamanid's major metabolites also do not have inhibitory activity against hepatic P450 enzymes at concentrations achieved with standard dosing.<sup>12</sup>

*In vitro* checkerboard assays have shown no evidence of antagonism with the first-line anti-TB drugs isoniazid, rifampin, ethambutol, or streptomycin,<sup>6</sup> although similar data have not been reported for drugs typically used to treat MDR or XDR TB. When given to healthy volunteers, rifampin was associated with a 47% decrease in delamanid area under the curve (AUC).<sup>8</sup> On the other hand, ethambutol levels increased by 25% when coadministered with delamanid, though the clinical significance of this change is uncertain.

Only limited data are available concerning delamanid's interactions with antiretrovirals. Delamanid has been reported not to have a significant effect on concentrations of tenofovir, lopinavir–ritonavir, or efavirenz.<sup>8,16</sup> Whereas lopinavir plus ritonavir was associated with a 20% increase in delamanid exposure<sup>16</sup> and a 30% increase in delamanid's metabolite DM-6705 (see discussion in “Toxicity” following), efavirenz coadministration did not have a significant effect on delamanid levels.<sup>8</sup> The effects of delamanid when administered with new protease inhibitors or members of other antiretroviral drug classes such as integrase inhibitors have not been reported.

## Murine studies

Delamanid has shown efficacy against drug-susceptible Mtb strains in both acute and chronic murine TB models, including studies with immunodeficient mice.<sup>6,17</sup> A delamanid-based regimen led to undetectable colony-forming units (CFU) in lung tissue at 4 months in a drug-susceptible murine model,<sup>6</sup> suggesting that delamanid might have treatment-shortening potential. However, a relapse study was not performed, so it was unclear whether the delamanid-based regimen indeed produced more rapid sterilization as compared with the standard multidrug regimen.

Unfortunately, similar data for MDR TB have not been published. By report, however, delamanid-based regimens were associated with improved survival in mice infected with an MDR Mtb strain; further details of this study have not been described.<sup>8</sup>

## Human studies

Diacon et al<sup>9</sup> assessed the early bactericidal activity (EBA) of four doses of delamanid (100, 200, 300, and 400 mg once daily) in human immunodeficiency virus (HIV)-negative persons with rifampin-susceptible TB. The average EBA for the delamanid groups was modest (0.04 log<sub>10</sub> CFU/mL sputum/day). No statistically significant differences between the groups were observed, with the caveat that the groups were small and there was significant intragroup variability in delamanid levels. In contrast, there did appear to be a relationship between EBA and delamanid levels; later unpublished work suggested that maximal EBA correlated with an AUC between 3,500 ng\*hr/mL and 5,500 ng\*hr/mL.<sup>18</sup> In the pharmacokinetic component of Diacon et al's<sup>9</sup> study, the investigators observed that delamanid exposure did not increase proportionate to dose and plateaued with 300 mg daily dosing.

In a subsequent, Phase II trial (Trial 204), 481 participants with MDR TB were treated with delamanid 100 mg twice daily, delamanid 200 mg twice daily, or placebo combined with an optimized background regimen (OBR) for 8 weeks and then followed for an additional 4 weeks with the OBR alone. The primary end point of this study was culture conversion on liquid media (mycobacteria growth indicator tube) at 8 weeks. Of note, the study excluded persons with baseline QT prolongation or conduction delay on electrocardiogram (ECG), as well as persons being treated with moxifloxacin. Few HIV-positive persons were enrolled (n=4); none was on antiretrovirals and all had CD4 counts of at least 350 cells/ $\mu$ L. The investigators found that both doses of delamanid were associated with increased rates of mycobacteria growth indicator tube culture negativity at 8 weeks (45.4% for delamanid 100 mg twice daily and 41.9% for delamanid 200 mg twice daily vs 29.6% for OBR alone); similar results were seen with solid media. In general, delamanid was well tolerated. Significantly higher proportions of participants receiving delamanid experienced QT prolongation, and the frequency appeared to be dose dependent (9.9% for delamanid 100 mg twice daily and 13.1% for delamanid 200 mg twice daily vs 3.8% for OBR alone); none of these cases was associated with clinical manifestations such as arrhythmia or syncope.<sup>19,20</sup>

Although culture conversion at 8 weeks (traditionally assessed on solid media) is a commonly accepted surrogate end point in trials for drug-susceptible TB,<sup>21</sup> its clinical significance for MDR TB is less established. However, observational studies have reported higher rates of good clinical outcomes (cure or completion of treatment) in MDR patients achieving culture conversion around 2 months,<sup>22,23</sup> suggesting that the higher rates of culture conversion at 8 weeks with delamanid-based regimens observed in Trial 204 may indeed be clinically meaningful.

In order to further assess the safety and efficacy of longer durations of delamanid treatment that would better represent its use in clinical practice, an open-label extension to Trial 204 was undertaken (Trial 208). In this investigation, participants were treated with an additional 6 months of delamanid at 100 mg twice daily (later increasing to 200 mg twice daily at the investigator's discretion) plus the OBR, starting at a minimum of 4 weeks after completing delamanid or placebo in Trial 204. There are two additional, important caveats to Trial 208, however. First, less than half (213/481, 44%) of Trial 204 participants had the option to participate in Trial 208 or chose to participate in Trial 208. Second, there was a significant delay in starting Trial 208 at many sites; at more than a third, the delay in starting delamanid was more than 4 months.<sup>8,18</sup>

Independent of their participation in the delamanid open-label extension study (Trial 208), participants in Trial 204 could be enrolled into an observational cohort for longitudinal follow-up (Study 116). Approximately 88% (421/481) of participants in Trial 204 chose to do so. In Study 116, participants were followed for up to 24 months following their first dose of delamanid in Trial 204 or until the end of MDR treatment, whichever came first. Treatment and monitoring in Study 116 were done according to local standard practice.<sup>18</sup>

Among Study 116 participants, a significantly higher proportion of persons who received delamanid at any dose for 6–8 months (ie, those who had participated in Trial 208) achieved a favorable outcome of cure or treatment completion compared with participants who received 0–2 months of delamanid (74.5% vs 55.0%). Mortality was also reduced among those receiving 6–8 months of delamanid (1% vs 8.3%).<sup>18</sup> Although these results are promising, serious limitations in the study design limit the conclusions that can be drawn from Trial 208 and Study 116. Most significant is the potential for selection bias. Participants in Trial 204 who did not elect to participate or have the opportunity to participate in Trial 208 may have been sicker or less adherent than those

who did choose to participate, which could account for lower rates of good clinical outcomes among persons receiving only 0–2 months of delamanid. Indeed, 8-week culture conversion rates were higher among Trial 204 participants who subsequently continued in Trial 208, compared with those who did not.<sup>8</sup> Unfortunately, no other data are published comparing characteristics of persons who participated or did not participate in Trial 208.

## Toxicity

Given the general poor tolerability of the drugs commonly used to treat MDR and XDR TB, it can be challenging to assign causality for reported adverse effects to new TB drugs. In clinical studies of delamanid, the most frequent adverse drug reactions include nausea (38%), vomiting (33%), and dizziness (30%). Other notable adverse reactions included tremor, paresthesia, and anxiety.<sup>13</sup>

While symptomatic management may mitigate these reactions, delamanid's potential to cause QT prolongation is more concerning. Indeed, patients undergoing treatment for MDR and XDR TB often have multiple other risk factors for QT prolongation,<sup>24</sup> such as electrolyte disturbances or treatment with other concomitant medications such as clofazimine, bedaquiline, or fluoroquinolones that have been associated with QT prolongation. As noted previously, approximately 10% of participants receiving delamanid in Trial 204 experienced QT prolongation, but only one individual developed QT prolongation over 500 ms. There was a trend toward more palpitations in the delamanid group, but more serious cardiac events were not observed. Of note, cases with QT prolongation over 60 ms were associated with concomitant fluoroquinolone treatment (either levofloxacin or ofloxacin, as moxifloxacin use was not permitted in Trial 204). Further analysis showed that risk of QT prolongation among persons receiving delamanid was strongly associated with hypoalbuminemia; albumin under 2.8 g/dL is therefore listed as a contraindication to delamanid treatment.<sup>13</sup>

Delamanid's effects on the QT interval appear to be dose related and increase over the initial 6–10 weeks of treatment. The effect has been linked to delamanid's major metabolite DM-6705. Both CYP3A4 inducers and inhibitors may increase levels of DM-6705, necessitating more intensive cardiac monitoring in such settings.<sup>8,13</sup> Current recommendations call for, at a minimum, a baseline and monthly ECG for persons on delamanid; delamanid is not recommended to be started or continued if the corrected QT interval is over 500 ms.<sup>13</sup>

## Ongoing and planned clinical studies

Planned or ongoing clinical studies will help address gaps in current knowledge relating to delamanid's use in MDR or XDR TB. A pediatric Phase I study will assess safety and pharmacokinetics of delamanid given for 10 days to 6- to 18-year-olds with MDR TB receiving an OBR (Otsuka 242-12-232, clinicaltrials.gov NCT01856634). Children aged 12–17 years will receive delamanid 100 mg twice daily, whereas children aged 6–11 years will receive 50 mg twice daily. A 6-month open-label study of delamanid plus OBR will follow the Phase I investigation, and younger age groups will also be included once the appropriate drug formulations are available.

A multisite Phase III clinical trial (Otsuka 242-09-213, clinicaltrials.gov NCT01424670) will evaluate a 6-month course of delamanid versus placebo plus OBR among adults with MDR TB. In contrast to earlier studies, delamanid dosing will be 100 mg twice daily for 2 months followed by 200 mg once daily for 4 months. A substudy of HIV-positive participants receiving antiretroviral therapy is planned as part of this trial.

## Remaining questions and conclusion

Delamanid is likely to provide a valuable addition to current therapies for MDR and XDR TB, yet multiple questions remain concerning its clinical use. First, the optimum duration of delamanid therapy is uncertain; limited quality data suggest that the duration should be at least 6 months,<sup>18</sup> but whether there would be additional benefit to longer treatment has not been established. It is also unclear whether the dose and schedule of delamanid approved by the European Medicines Agency, 100 mg twice daily, is the most appropriate; further studies are planned to assess this question.<sup>8,25</sup> Furthermore, delamanid's ability to protect against emergence of resistance to other coadministered anti-TB drugs and its interactions with newer antiretroviral regimens remain to be studied. As is the case for most other TB drugs, it is unclear which agents would be the most effective and least toxic when paired with delamanid to treat MDR or XDR TB.<sup>26</sup>

Given delamanid's potential to prolong the QT interval, monitoring for cardiac toxicities will be essential as the drug is studied in larger patient populations. How and whether it can be safely used with other anti-TB drugs that have QT-prolonging potential, such as bedaquiline, clofazimine, and newer-generation fluoroquinolones such as moxifloxacin is an important unanswered practical question for TB clinicians. These cardiac concerns will restrict delamanid's

use to health centers that are comfortable performing and interpreting ECGs.

The failure of fluoroquinolone-based regimens to permit treatment shortening for drug-susceptible TB has raised concerns about the predictive value of sputum culture conversion rates for relapse-free TB cure in the modern era.<sup>27</sup> It will therefore be important to more rigorously determine whether delamanid-based regimens indeed translate into improved clinical outcomes and lower overall mortality in patients with MDR or XDR TB.

Despite these outstanding questions, the medical need for improved MDR and XDR therapies is great, and the published data for delamanid are promising. These considerations led to the conditional marketing approval of delamanid by the European Medicines Agency in 2014. TB clinicians and patients await further results from the ongoing clinical studies of delamanid with great interest.
