Periodontal health and diabetes awareness among Saudi diabetes patients

Maha A Bahammam

Department of Periodontology, King Abdulaziz University Faculty of Dentistry, Jeddah, Kingdom of Saudi Arabia

Purpose: This study aimed to examine diabetic patients in Jeddah, Saudi Arabia, regarding their general diabetic and oral health-related awareness and practices, their awareness of the association of diabetes with periodontal disease, and their sources of diabetes-related information.

Methods: Diabetic patients (n=454) who were receiving care at the diabetes clinic in King Abdulaziz University Hospital, Jeddah, Saudi Arabia, from October 2013 to May 2014, completed a six-part questionnaire assessing their sociodemographic characteristics, general and oral health awareness and practices, and sources of diabetes-related information. Descriptive statistics were used to report the results.

Results: The responses indicated inadequate health-related practices in the surveyed group: 22.2% brushed their teeth twice daily, 73.6% never flossed their teeth, and while 80.2% visited a physician in the past year, only 12.6% visited a dentist during the same year. Of the respondents, 94.8% reported that they had never received advice on oral hygiene tasks in relation to diabetes from a health professional. Awareness about the diabetes and periodontal disease association was limited: 46.7% knew that diabetics have gum problems more often if their blood sugar stays very high, and only 21.8% knew that gum disease makes it harder to control blood sugar in diabetic patients. A significant association (P<0.05) was found between a higher level of education and greater general and oral awareness, as well as a significant association (P<0.05) between longer duration of disease, regular exercise, and regular visits to the physician and awareness about diabetes mellitus. Additionally, a significant association (P<0.05) was found between regular dental visits and both periodontal disease and diabetes awareness. Family and friends were the main source of diabetes-related information, and the Internet was the least likely source.

Conclusion: Customized educational programs should be planned for diabetic patients according to community needs.

Keywords: periodontal health, diabetes, patients, awareness, Saudi Arabia

Introduction

Diabetes mellitus encompasses a group of metabolic disorders that result in acute and chronic complications due to the absolute or relative lack of insulin. Diabetes has reached epidemic proportions worldwide, and its prevalence is increasing rapidly. In 2000, an estimated 2.8% of all age groups worldwide were suffering from diabetes. This number is estimated to be 4.4% in 2030.1

In Saudi Arabia, diabetes mellitus has one of the highest prevalence rates. The overall prevalence of diabetes mellitus among Saudi adults of both sexes in rural as well as urban communities is 23.7%, with 26.2% being males and 21.5% females, as reported by a community-based national epidemiological health survey published in 2004.2

Long-term poor glycemic control in diabetes is the principal cause of major complications including diabetic nephropathy, retinopathy, coronary heart disease, and strokes.3

Moreover, studies indicate that diabetic patients are two to three times more likely to develop periodontal disease\textsuperscript{4–8} and display a greater severity of periodontal disease.\textsuperscript{9}

An extensive body of research has proven a bidirectional relationship between periodontal disease and diabetes.\textsuperscript{10,11} Uncontrolled diabetes with poor glycemic control is a risk factor for severe periodontitis. The treatment of periodontitis improves glycemic control.\textsuperscript{12} Considering this important relationship between periodontal disease and diabetes, effective behaviors to prevent and control periodontal disease such as brushing, flossing, and routine dental visits not only have a positive impact on improving periodontal health\textsuperscript{13} but must also be considered as integral for diabetic patients’ health.\textsuperscript{14}

Several studies have investigated the awareness of diabetic patients regarding their periodontal health and the increased risk for periodontal disease. In a controlled study conducted in Sweden, 83% of diabetic patients were found to be unaware of the link between periodontal disease and diabetes.\textsuperscript{15} Moreover, a cross-sectional study that was conducted in 38 states in the USA showed that diabetic patients are less concerned with their oral health and were less likely to have seen a dentist than nondiabetic patients.\textsuperscript{16} Another study conducted in the USA involving 390 patients with diabetes found that only 18.2% recognized that their oral health might be affected by diabetes.\textsuperscript{17} A community trial in Finland concluded that self-reported twice-daily tooth brushing is less frequent in diabetic patients than in nondiabetic patients.\textsuperscript{18}

In the Arab countries, a study conducted on a random sample of 405 diabetic patients in Jordan showed that approximately 48% were aware that diabetic patients are more susceptible to periodontal diseases and oral health complications, and approximately a third (38%) knew that periodontal treatment may help in controlling diabetes.\textsuperscript{19}

In Saudi Arabia, currently, little is known about the knowledge of risk for periodontal disease and the awareness of oral health in diabetic patients. In one survey conducted in Riyadh, Saudi Arabia, of female Saudi diabetic patients assessing their knowledge and attitude regarding oral health, it was found that the majority of these diabetic patients lacked knowledge about the relationship between diabetes and periodontal health.\textsuperscript{20} A more recent study conducted in Abha, Saudi Arabia, illustrated that there is deficiency in the awareness and dental health knowledge among diabetic patients. The results showed that 52.3% of the participants were not aware that diabetic patients are more susceptible to oral diseases.\textsuperscript{21}

Given these findings and the alarming high prevalence of diabetes in Saudi Arabia, further research is needed to assess the association of periodontal disease and diabetes and to develop preventive strategies to control this problem. The aim of this study was to examine diabetic patients for the following: 1) general diabetic and oral health-related awareness and practice; 2) awareness of diabetes and its association with periodontal disease; and 3) sources of diabetes-related information in Jeddah, Saudi Arabia.

**Materials and methods**

**Sample**

This study was a cross-sectional descriptive survey of 454 subjects with known diagnosis of diabetes mellitus who were registered at the diabetes clinic in King Abdulaziz University (KAU) Hospital, Jeddah, Saudi Arabia. The majority of patients attending this hospital are Saudis from a mixture of urban and rural communities, with varying socioeconomic backgrounds. The study was conducted from October 2013 to May 2014. Diabetic patients needed to fulfill the following two conditions to be included in this study: 1) the presence of at least one natural tooth in the patient’s mouth and 2) the patient had been diagnosed with diabetes for at least 6 months. Diabetic medical personnel or patients with obvious physical or mental illnesses were excluded from this study. Patients of all age groups were included in the sample.

**Questionnaire**

A structured questionnaire was designed based on a thorough review of the literature on diabetes and periodontal disease.\textsuperscript{22–27} The questionnaire consisted of six parts. The first part of the survey assessed sociodemographic characteristics (sex, age, nationality, and education). The second part assessed participants’ medical history including type of diabetes, medications used, duration, and family history of the disease. The third part assessed participants’ general health and oral hygiene practices including participants’ physical activities (ie, exercise), recent testing for blood glucose, regularity of visits to physician and dentist, brushing and flossing frequency, and other questions concerning previous advice to participants by medical personnel. The fourth part assessed participants’ general awareness of diabetes concerning diet, causes of diabetes mellitus, types of diabetes, and blood glucose level. The fifth part assessed the periodontal–diabetes association, including questions addressing the bidirectional relation between periodontitis and diabetes mellitus and its relationship to smoking and to blood glucose levels. Items in the fourth and fifth parts were multiple-choice questions with three answer options for every given statement: true, false, or do not know. On the sixth and last parts of the questionnaire, participants were questioned regarding their sources of diabetes information. Options given...
in this section were friends or family, a health care provider, newspapers, magazines or books, television, the Internet, or school. The questionnaire was reviewed for appropriate wording by expert colleagues at KAU. Subsequently, the questionnaire was piloted on 30 patients to determine time required and readability. The study protocol was approved by the Research Ethics Committee of KAU Faculty of Dentistry. All diabetic patients entered the study voluntarily, following an explanation of its purpose and objectives. Informed verbal consent was obtained from each eligible participant prior to data collection. The data were collected by interviewing the participants; investigators asked the questions verbally and completed the form. Interviewers were trained to achieve consistency among them. Privacy of the patients was ensured, and at the end of questioning, the patients were informed about the impact of their systemic condition on oral health and vice versa.

Statistical analysis
Descriptive statistics were used to report the results regarding the participants’ sociodemographic data, medical history, participants’ general and oral health awareness and practices, participants’ awareness and healthy behavior, and participants’ sources of diabetes-related information.

Wilcoxon Mann–Whitney test was used for comparison of the awareness distributions in the case of two groups, and Kruskal–Wallis test was used in the case of more than two groups. All tests were two sided with \( P<0.05 \) set as the significance level. All analyses were conducted using SPSS version 16 (SPSS Inc., Chicago, IL, USA).

Results
Distribution of the study population
Sociodemographic characteristics of the participants
A total of 454 (231 males and 223 females) out of 522 registered diabetic patients completed the diabetes awareness assessment questionnaire for a response rate of 87%. The highest percentage of the respondents were between 40 years and 39 years of age (41.4%), and 39.6% were between 20 years and 39 years of age. With regard to their nationality, 85.7% were Saudis, and 14.3% were non-Saudis; 45.8% of the participants had college education (Table 1).

Medical history
Most of the participants suffered from type 2 diabetes (85.8%), and only 14.2% suffered from type 1. The majority were taking oral hypoglycemic medication (69.3%), and the rest were taking either insulin alone (19.4%) or both insulin and oral hypoglycemic (11.3%). Regarding the length of time since participants had been diagnosed with diabetes, 42.2% had the disease for more than 10 years. Regarding family history of diabetes, 77.7% of those with a positive history reported a first-degree relative (ie, a parent or sibling), and 13.5% reported a second-degree relative with the disease (Table 1).

General and oral health-related awareness and practices
General health and oral hygiene practices
As shown in Table 2, the responses indicated inadequate health-related practices in the surveyed group. Only 13.2% of participants exercised daily, while 46.5% rarely exercised and 40.3% never exercised. Only 30% of these participants indicated that they had a recent test for blood glucose on the same day of the interview; 10.8% had a glucose test within

**Note:** n=454.

the last week, and 38.3% of them had a glucose test within the last month. Although 80.2% of participants visited a physician for follow-up in the last year, only 12.6% visited a dentist regularly during the same year.

Regarding oral hygiene practices, the majority of the respondents (65.4%) brushed their teeth once a day, 22.2% brushed their teeth twice a day, and 7.8% of the respondents brushed their teeth less than once a day. Flossing habits were rated less important as most of the respondents reported that they never flossed their teeth (73.6%). Regarding health care professionals’ involvement in dental care, 94.8% of respondents reported that they had never received advice on oral hygiene tasks in relation to diabetes from a health professional, and 74.9% of them stated that their dentists had...
adviced them to monitor diabetes. Oral health awareness and advice received are shown in Table 2.

**General diabetes mellitus awareness**

As seen in Table 2, the participants’ responses were variable regarding the diabetes diet. The majority of the respondents (96%) responded correctly to the question “Patients must eat a healthy diet”, but only 11.9% responded correctly to the question “Patients must eat a high-protein diet” and 43.8% responded correctly to the question “Patients must eat a high-carbohydrate diet”.

Regarding the causes of diabetes mellitus, 79.7% responded to the item “increased blood sugar level” correctly, and 41.4% responded to the item “body unable to make sugar” correctly. Most of the participants’ answers were correct (81.5%) regarding overweight being a cause for diabetes, but only 19.4% answered correctly as to whether eating too many sweets leads to diabetes.

Approximately 78.6% of the participants’ answers were correct regarding the number of types of diabetes, and 73.8% could correctly identify that a fasting blood glucose of 250 mg/dL is too high.

**Participants’ awareness on the association between periodontal disease and diabetes**

As can be seen in Table 2, nearly half of the participants (46.7%) knew that diabetics have gum problems more often if their blood sugar stays very high, but only 21.8% knew that gum disease makes it harder to control blood sugar in diabetic patients. Moreover, the majority of the participants (67.2%) knew that people with diabetes who smoke are more likely to develop severe gum disease than nonsmokers with diabetes, and almost half of the participants (47.8%) knew that people with diabetes are more likely to have periodontal disease than those without diabetes.

**Participants’ awareness and healthy behavior**

As shown in Table 3, participants with a higher level of education had significantly greater general awareness about diabetes mellitus (P=0.000) and significantly greater awareness of the association between periodontal disease and diabetes compared to those with school-level education (P=0.026). Those with a longer duration of the disease, those who regularly exercised, those who visited their physicians during the last year, and those who obtained their information from health care providers were significantly more likely to have greater general awareness about diabetes mellitus (P<0.05). In addition, those participants who reported regular dental visits were more likely to be aware of the association between periodontal disease and diabetes (P<0.05).

Regarding source of diabetic-related information, those who obtained their information from health care providers had significantly greater general awareness about diabetes mellitus (P=0.000), but awareness of the association between periodontal disease and diabetes was not associated with this source of information (P=0.075). As for the other sources

of information, the association results were not significant (data not shown).

**Sources of diabetes-related information**

All the 454 participants who completed the diabetes awareness assessment questionnaire responded to the question asking how they had learned about diabetes. As shown in Figure 1, more than half of the participants (55.3%) had learned about diabetes from family or friends. Just over half got their information from health care providers (50.9%). Only 34.8% of the participants obtained their information from print materials or from television (29.5%). Over half of the participants learned about diabetes from the Internet (52.2%), and only 9.3% gained their information from school.

Participants with a longer duration of disease, those who reported regular exercise, and those who reported regular visits to the physician had more awareness of diabetes mellitus. Participants who reported regular dental visits were more aware of the bilateral association between periodontal disease and diabetes mellitus.

**Discussion**

To the best of our knowledge, this is the first study in Saudi Arabia that thoroughly and comprehensively documents diabetic patients’ general awareness about diabetes mellitus and its association with periodontal disease, as well as their health behavior and their sources of diabetic-related information.

This study revealed that most of these diabetic participants visited their physician in the last year (80.2%), but they were not compliant with dental visits, with only 12.6% visiting their dentists regularly. The low compliance with regular dental visits shown in the present study is consistent with previous research conducted with female Saudi adults which showed that only 8% of female diabetic patients visited their dentist on a regular basis and with another survey conducted with diabetic patients in Jordan that showed only 10% of participants attended their dental appointments regularly. Our results regarding dental visit compliance are lower than those reported in other research (39% and 43%, respectively). The difference between our study and the latter studies, which were conducted in Western countries, could be due to the different populations investigated.

Based on the participants’ physician and dentist visit results, this survey clearly shows that oral health is not a major priority for this particular group of diabetic patients. Moreover, the compliance with dental visits was less than that found in Western countries. Thus, diabetic patients’ regular visits to the dentist for reinforcement and education on oral health information should be encouraged in all diabetic centers. Diabetic patients should also be educated about the oral and systemic complications of diabetes, in an effort to meet the national health objective set by the USA, which was by 2010 to increase to 71% the proportion of people with diabetes who have an annual dental checkup.

The findings that only 22.2% of the participants brushed their teeth twice daily, only 65.4% brushed their teeth once daily, and the majority of participants (73.6%) never used dental floss to clean between their teeth indicate that oral hygiene measures are not a routine practice in this population.
Furthermore, encouragement of proper oral hygiene methods together with education concerning their use should be undertaken in order to enhance periodontal health and prevent gingival diseases in this high-risk population. Similar findings of inadequate oral hygiene in diabetic patients have been shown by other investigators.  

The findings that none of the participants in this survey had ever been advised by their physicians to brush their teeth and only 5.2% had received advice from a physician to see their dentist regularly suggest a huge underestimation among physicians of the importance of oral health for diabetic patients. Dentists, physicians, and other health care providers should provide accurate and easily understandable material for diabetic patients about the association between diabetes and oral health and should encourage all diabetic patients to seek oral health examinations. Diabetic patients should be informed that, through preventive oral health measures, periodontal diseases can be minimized or avoided and diabetic control outcomes could be improved.

The results suggest that patients of the diabetic center of the KAU Hospital had considerable awareness of general diabetes information. This awareness of general diabetic items could be attributed to their having regular routine physician visits. However, as for awareness of the relationship of diabetes with periodontal disease, only 68% of the participants were aware that diabetics would have gum problems more often if their blood sugar remained high. These findings indicate that participants in the present study were less aware regarding the possible connection between periodontal diseases and diabetes and did not recognize that the presence of diabetes increased the risk of periodontal diseases. This lack of awareness of the association between periodontal disease and diabetes within the diabetic group examined is notable, especially in light of their general diabetes awareness. This result was consistent with the results of other studies conducted in Saudi Arabia and other countries showing that knowledge of the relationship of diabetes with periodontal disease is lacking.

Friends and family were the most useful source of information about diabetes (55.3%), followed by the Internet (52.2%). Thus, most of the information obtained by the diabetic patients came from informal sources lacking a scientific basis. This suggests that oral health educational material for diabetic patients containing accurate and updated information needs to be available through educational programs for diabetic patients. However, regardless of the information source, it is clear that the study sample’s awareness of the association between periodontal disease and diabetes was limited.

An outcome that was not the main aim of this study was the finding that participants with longer duration of the disease, those who regularly exercised, and those who visited their physicians during the last year were more likely to have greater general awareness about diabetes mellitus. This could be explained by the fact that with longer duration of exposure to health care personnel, patients become more concerned about their medical condition. In addition, those participants who reported regular dental visits were more likely to be aware of the association between periodontal disease and diabetes. This might be attributed to the increased level of attending dental clinics. Similarly, in a study conducted by Al Habashneh et al it was found that diabetic patients with healthier lifestyle behaviors were more likely to have knowledge of the association between diabetes and oral health. However, findings on dental and physician visits as well as general awareness about diabetes mellitus were not reported in any other previous studies to allow comparison with the present study.

This survey reveals that the awareness of diabetes and periodontal disease is poor. Thus, diabetic patients need to be better informed of their risk for periodontal disease and to have an increased awareness of the importance of oral health in their overall general health and well-being. Improving awareness and thus changing health-related behavior and preventing complications cannot be achieved without health education. Health education attempts to change behaviors by altering an individual’s awareness, attitudes, and beliefs about health matters to involve patients in caring for themselves. Studies on the impact of diabetes health education in terms of metabolic control in Saudi Arabia are very few, and almost all of these studies were conducted to determine the role of knowledge and attending an education program on patients’ glycemic control. Therefore, our research findings make it necessary to carry out more research in Saudi Arabia to identify the barriers to awareness and compliance of diabetic patients. Further research could encourage government and private health care providers as well as insurance companies to establish a system that facilitates annual dental visits for all diabetic patients, in keeping with the objectives of the US National Institutes of Healthy People 2010 initiative.

One of the potential causes of patients’ lack of awareness might be a lack of knowledge among dentists and physicians regarding the association between periodontal diseases and diabetes mellitus. Future studies should be conducted in Saudi Arabia to test the knowledge of health care providers on the association between periodontal diseases and diabetes.
Moreover, it is of paramount importance for dental professionals and health care providers to keep up with current knowledge, since it is fast evolving. Dental and clinical practitioners should integrate their efforts and participate in education at an organizational level in an effort to raise awareness of oral health issues within the diabetic population.

This study provides many useful and practical insights concerning the factors influencing awareness of the association between diabetes and periodontal health among diabetic patients in Jeddah, Saudi Arabia. This study has three potential limitations. First, we used a nonrandom convenience sample of diabetic patients from the Diabetic Center of KAU Hospital. As such, it is unclear as to what extent the results are representative of diabetic patients in other university-based clinics or in periodontal practice settings in diverse geographic locations. A more heterogeneous sample from diabetic centers of different hospitals in the region and in other regions in Saudi Arabia would have improved generalization of the results. Second, the results of the study reflect a population with low dental attendance (mainly for symptomatic care). Some bias may have been present in the overall periodontal responses as opposed to general diabetic responses due to the recruitment of the diabetic patients from a diabetic outpatient clinic – the results may therefore not be representative of the whole diabetic population. A third limitation may be the accuracy of the collected data. Data collection was dependent on the participants’ responses to the interview questionnaire without review of their medical or dental charts or any official records. Nevertheless, interviewing the participants has an advantage over a self-reported questionnaire in that it avoids their misunderstanding of any questions. No oral examination or laboratory tests were used to ensure validity of the findings. Therefore, our results can hardly be generalized to a broader population with more diverse education, higher levels of oral health knowledge and practice, or more intensive management of the diabetic condition. Finally, answers may be subject to recall bias due to the possibility of participants giving socially acceptable responses to questions pertaining to oral health practice. However, this study provides additional evidence that diabetic patients have limited awareness of the potential impact of poor oral health on their general health.

Despite these limitations, our data suggest that awareness about diabetes and its association with periodontal disease may be limited among diabetic patients. These results support the need for education on the periodontitis–diabetes relationship for these at-risk patients. The clinical implication of our findings is that dentists, physicians, and other health providers should recommend that a diabetic patient see a dentist regularly. Dental practitioners have an opportunity and a responsibility to educate diabetic patients about the oral complications of diabetes and to promote proper oral health behaviors. Future patient education requires ingenuity and the commitment of necessary resources to improve outcomes with diabetic patients.

**Conclusion**

These findings of limited awareness regarding diabetes and periodontitis indicate that this topic is still neglected, and immediate actions should be taken.
