Clinical utility of eslicarbazepine: current evidence

Gaetano Zaccara¹Fabio Giovannelli^{1,2}Massimo Cincotta¹Alessia Carelli³Alberto Verrotti³¹Department of Medicine, Unit of Neurology, Florence Health Authority, Florence, Italy;²Department of Neuroscience, Psychology, Pharmacology and Child Health (NEUROFARBA), University of Florence, Florence, Italy;³Department of Pediatrics, University of Perugia, Perugia, Italy

Abstract: Eslicarbazepine acetate (ESL) is a new antiepileptic drug whose mechanism of action is blockade of the voltage-gated sodium channel (VGSC). However, in respect to carbamazepine and oxcarbazepine, the active ESL metabolite (eslicarbazepine) affects slow inactivation of VGSC and has a similar affinity for the inactivated state and a lower affinity for the resting state of the channel. This new antiepileptic drug has been recently approved in Europe (trade name Zebinix) and in the United States (trade name Stedesa) for adjunctive treatment in adult subjects with partial-onset seizures, with or without secondary generalization. Following oral administration, ESL is rapidly and extensively metabolized by hepatic esterases to eslicarbazepine. This active metabolite has a linear pharmacokinetic profile, a low binding to plasma proteins (<40%), and a half-life of 20–24 hours and is mainly excreted by kidneys in an unchanged form or as glucuronide conjugates. ESL is administered once a day and has a low potential for drug–drug interactions. Efficacy and safety of this drug in patients with focal seizures have been assessed in four randomized clinical trials, and responder rates (percentage of patients with a $\geq 50\%$ improvement of their seizures) ranged between 17% and 43%. Adverse events were usually mild to moderate, and the most common were dizziness, somnolence, diplopia, abnormal coordination, blurred vision, vertigo, headache, fatigue, nausea, and vomiting. ESL may be considered an interesting alternative to current antiepileptic drugs for the treatment of drug-resistant focal epilepsies. Additionally, it is under investigation in children with focal epilepsies, in patients with newly diagnosed focal epilepsies, and also in other neurological and psychiatric disorders.

Keywords: antiepileptic drugs, epilepsy, eslicarbazepine acetate, pharmacoresistant epilepsy, oxcarbazepine, carbamazepine

Introduction

Epilepsy has an annual incidence of about 50 per 100,000 and a prevalence between 5 and 10 per 1,000.¹ Treatment of this common neurological disorder is mainly symptomatic, with antiepileptic drugs (AEDs) considered to be the main therapeutic approach. However, despite a broad range of commonly used AEDs, approximately 30% of adult patients with epilepsy have their seizures uncontrolled.² Most importantly, adverse effects are a major deterrent to successful treatment with AEDs. In patients with epilepsy, it has been shown that they negatively impact on health-related quality of life, are a significant source of disability, and morbidity,^{3–5} and may lead to treatment discontinuation in up to 25% of patients^{6–8} or a low adherence to the treatment.^{8,9}

Eslicarbazepine acetate (ESL) is a third-generation member of the dibenzazepine family, which also includes carbamazepine (CBZ) and oxcarbazepine (OXC).^{10–13} It has been approved in 2009 by the European Medicines Agency and in 2013 by the US Food and Drug Administration as adjunctive therapy in adults with partial-onset seizures with or without secondary generalization. It is available in Europe in the pharmaceutical form of tablets under the trade name Zebinix (produced by BIAL, Trofa, Porto District, Portugal) and in the United States under the trade name Stedesa

In respect to CBZ and OXC, ESL may be used with a simplified drug regimen, and there are some data that suggest an improved tolerability profile.

Mechanisms of action and pharmacokinetics

Mechanisms of action

All AEDs exert their effect through a reduction of membrane excitability, which is the consequence of interaction with ion channels or neurotransmitter receptors. Blockade of voltage-gated sodium channel (VGSC) is the proposed mechanism of action for various AEDs, such as CBZ, lamotrigine, OXC, and phenytoin,¹⁴ and ESL shares with these AEDs the characteristic of being a potent blocker of VGSC.¹⁰

It has been recently shown that there are some differences between AEDs in the way this effect is achieved. VGSC has three distinctive states: resting state, open state, and inactivated state. During the resting or deactivated phase, the VGSC is closed, but it opens in response to a depolarization impulse. This allows the entrance of sodium ion into the cell and generates the action potential. Immediately after the action potential, the channel goes for a few milliseconds into inactivated state, in which it is closed again but cannot be opened because it is not responsive to voltage changes.¹⁵

The suggested mechanism for those AEDs acting on VGSC is to prolong the inactivated state of the sodium channel, thus preventing its reversion to the resting form and a possible further depolarization. The consequence is that they limit sustained repetitive neuronal firing.^{11,16,17}

However, the affinity of a drug for the channel may be different in different functional states of the channel, and different VGSC blockers may behave differently. In fact, the affinity of ESL for the inactivated state of the VGSC is similar to that of CBZ, while the affinity of ESL for the resting state of the channel is about three times lower than that of CBZ. As a consequence, ESL should be equally effective in preventing sustained repetitive neural firing but less effective in disturbing physiological mechanisms.¹⁸

Other important differences have been recently demonstrated between AEDs acting on VGSC. It is known that there are at least two distinct kinetic classes of inactivation, termed fast and slow.

Within milliseconds of depolarization, the channels enter the fast-inactivated state which is characterized by closure

of the channel pore, which does not reopen until the cell is hyperpolarized.¹⁹ During fast inactivation, a cytoplasmic region (the inactivating particle) occludes the pore²⁰ and makes the cell refractory to firing.^{20,21} Slow inactivation is a separate process that appears after prolonged depolarization, does not involve the inactivating particle, and may result from a structural rearrangement of the pore.¹⁹ Fast inactivation of Na channels is thought to contribute to action potential termination and regulation of the refractory period,²² while slow inactivation, which occurs on a much slower time scale of seconds, is thought to contribute to overall membrane excitability by increasing action potential thresholds, thereby limiting action potential burst durations and, most importantly, their propagation within dendrites.^{23,24}

Although the majority of VGSC blockers used in the treatment of epileptic seizures interfere with the fast inactivation pathway, there is information that suggests that some AEDs may influence the slow inactivation of VGSC.²⁰ For example, lacosamide (LCM) was shown to act by enhancing slow inactivation of VGSC.²⁵

Recently, the effect of ESL, CBZ, OXC, and LCM on the fast and slow inactivated states of VGSCs has been evaluated in an experimental study,²⁶ and it has been observed that both ESL and LCM reduce VGSC availability through enhancement of slow inactivation, while these AEDs do not share with CBZ and OXC the ability to alter fast inactivation of VGSC.

In conclusion, ESL is a VGSC blocker which, in respect to CBZ, has a similar affinity for inactivated state of the channel and a lower affinity for the resting state. Furthermore, in respect to CBZ and OXC, ESL affects slow inactivation and not fast inactivation of VGSC. Both these characteristics would suggest similar effect on sustained repetitive neural firing with a lower propensity in disturbing physiological mechanisms.

In animal models, ESL is effective against seizures induced by proconvulsant agents such as metrazole, bicuculline, 4-aminopyridine, and picrotoxin,^{11,27,28} and is also effective in the amygdala-kindled rat model.¹¹ In these models, ESL was equipotential to CBZ and more potent than OXC, showed less neurological impairment in rats, and was less toxic to cultured hippocampal neurons.²⁹ The ESL activity profile in animal models predicts efficacy in partial and generalized tonic-clonic seizures in humans.¹¹

Pharmacokinetics

Following oral administration, absorption of ESL from the gastrointestinal tract is high. In fact, it has been shown that

the amount of metabolites recovered in urine corresponded to more than 90% of the administered ESL dose.¹² After the absorption, the drug is rapidly and extensively metabolized by hepatic esterases to eslicarbazepine (also known as *S*-licarbazepine), which is the major ESL metabolite and is responsible for the pharmacological effect.¹² As a consequence, plasma ESL concentration always remains below the limit of detection (Table 1).¹¹

Concomitant intake of ESL with food does not influence absorption.³⁰ Peak plasma eslicarbazepine concentrations are attained at 2–3 hours post-dose, and steady-state plasma concentrations are attained after 4–5 days of once-daily dosing, consistent with an effective half-life in the order of 20–24 hours.^{12,31,32}

Binding of eslicarbazepine to plasma proteins is relatively low (<40%) and is not affected by other coadministered drugs.^{11,32}

A minor ESL metabolite in plasma is the right isomer of eslicarbazepine, *R*-licarbazepine, which is inactive. A small amount of both stereoisomers, eslicarbazepine and *R*-licarbazepine, undergo chiral inversion through metabolic oxidation to OXC.³³

ESL does not affect its own metabolism,³⁴ and its pharmacokinetic parameters are dose-proportional across the dose range of 400–2,400 mg/d in healthy subjects³⁵ and in patients.³⁶ Finally, ESL and its metabolites are eliminated from the systemic circulation primarily by renal excretion, and approximately two-thirds of them are in the unchanged form and one-third as glucuronide conjugates.

Special populations

ESL pharmacokinetic profile has been specifically assessed in children and adolescents,³⁶ and no relevant differences have been found in respect to adults, although dose-normalized C_{max} and AUC depended on age, indicating faster

clearance in younger children than in adolescents.¹² The pharmacokinetic profile of ESL is not significantly affected by old age³² and sex.³⁷

The effect of renal function on ESL pharmacokinetics has been studied in patients with mild, moderate, and severe renal function impairments,³⁸ and a significant relationship has been found between creatinine clearance (CrCl) and eslicarbazepine renal clearance. The excretion of other ESL metabolites (eslicarbazepine–glucuronide, (*R*)-licarbazepine, (*R*)-licarbazepine–glucuronide, OXC, and OXC–glucuronide) is also significantly affected by kidney diseases. Values of creatinine clearance between 30 and 60 mL/min should require half the dose, while data are insufficient to establish a recommendation for dose adjustment in patients with CrCl <30 mL/min.³⁸ Finally, hemodialysis partially removes ESL from plasma.³²

Liver function has less critical effects on ESL kinetics. In patients with a moderate liver impairment, ESL pharmacokinetics was not significantly affected, although there were more subjects with measurable plasma ESL concentrations in the hepatic impairment group than in the control group.³⁹ Biotransformation of ESL to eslicarbazepine during first passage does not seem to be affected by portal-systemic shunting. Glucuronide metabolites are also unchanged in patients with moderate liver disease.³⁹

Drug interactions

In vitro, ESL is a weak inducer of cytochrome P450 3A4 (CYP3A4) and UDP-glucuronyl transferases. Thus, an increase in the dose of the medical products that are mainly metabolized through CYP3A4 or through the UDP-glucuronyl transferases may be required when coadministered with ESL.^{12,32} ESL has also inhibiting properties with respect to CYP2C19, which might require dose adjustments of coadministered drugs metabolized by this enzyme (eg, phenytoin, clopidogrel, omeprazole, and diazepam).¹²

Interactions with other AEDs

Data from healthy subjects have shown that concomitant administration of ESL 1,200 mg once daily with the enzyme inducers phenytoin or CBZ resulted in an average decrease of 31%–33% in exposure to eslicarbazepine, most likely caused by an induction of glucuronidation.¹² On the basis of individual response, the dose of ESL may need to be increased when coadministered with these drugs. An average increase of 31%–35% in exposure to phenytoin, most likely caused by an inhibition of CYP2C19, has also been observed in these patients, which may require a reduction of phenytoin dose.^{12,32}

Table 1 Pharmacokinetic and metabolism of the active metabolite eslicarbazepine

T_{max}	2–3 h
Bioavailability	High
$T_{1/2}$	20–24 h
Pharmacokinetics	Linear over the dose range of 400–2,400 mg/d
Protein binding	<40%
Metabolism	Minor metabolites in plasma are <i>R</i> -licarbazepine and oxcarbazepine. Other minor metabolites are glucuronic acid conjugates of eslicarbazepine, <i>R</i> -licarbazepine, and oxcarbazepine.
Excretion	Urinary excretion

Notes: Data from Almeida and Soares-da-Silva¹¹ and Bialer and Soares-da-Silva.¹²

Abbreviations: T_{max} , time to achieve peak concentration; $T_{1/2}$, half life.

Similar studies on healthy volunteers showed minor pharmacokinetic interactions between ESL and lamotrigine, and ESL and topiramate (with a 15% reduction to the exposure to lamotrigine and an 18% reduction to the exposure to topiramate).¹²

A population pharmacokinetic analysis in epileptic adult patients has indicated that a concomitant administration of this agent with valproate or levetiracetam does not affect the exposure to eslicarbazepine.^{32,40}

Interactions with other medicinal products

Administration of ESL 1,200 mg once daily to female subjects using a combined oral contraceptive showed an average decrease of 37% and 42% in systemic exposure to levonorgestrel and ethinylestradiol, respectively, most likely caused by an induction of CYP3A4. Therefore, women of childbearing potential should use other adequate methods of contraception during treatment with ESL.⁴¹

A reduction of systemic exposure to simvastatin and rosuvastatin (50% and 36%–39%, respectively) has been observed in healthy subjects when ESL is coadministered with these statins.^{12,32}

Coadministration of ESL with warfarin also was found to cause a mild (23%) but statistically significant decrease in (*S*)-warfarin plasma exposure, with no significant effect on the (*R*)-warfarin pharmacokinetics or coagulation.⁴² However, due to interindividual variability in the interaction, special attention should be directed to INR (international normalized ratio) monitoring during the first weeks of initiation or at the end of concomitant warfarin–ESL treatment.³³ No interaction has been observed between digoxin and ESL in healthy volunteers.¹²

Since ESL and OXC exert their effects through an identical metabolite, which is eslicarbazepine, it may be important to underline kinetic differences between these two AEDs.

The first difference is that, after OXC administration, a peak concentration of the parent drug is detectable in plasma, with a half-life of 1–2.5 hours,⁴³ and also in the cerebrospinal fluid.⁴⁴ This OXC peak concentration may produce an effect in brain before transformation to its active metabolite (it should be remembered that OXC affects fast inactivation of VGSC). In contrast, after ESL administration, the agent is rapidly converted to eslicarbazepine and is not even detectable in plasma.^{18,31}

A further point is that OXC is transformed to equal amounts of both stereoisomers of which one is active (eslicarbazepine) and the other is inactive (*R*-licarbazepine), whereas ESL is mainly transformed to the active metabolite.

This results in a 40% increase in the delivery of the active metabolite eslicarbazepine into the plasma as well as a significantly lower systemic exposure to the inactive (*R*)-licarbazepine when compared with OXC.³⁵

Experiences in adults: efficacy, tolerability, and safety

For the assessment of ESL efficacy and tolerability as an add-on drug in focal epilepsies, 1,192 adult patients with drug-resistant focal epilepsies were recruited in one Phase II⁴⁵ and three Phase III^{46–48} studies. In all studies, patients with at least four simple or complex partial-onset seizures per month despite treatment with 1–2 or 1–3 AEDs could be recruited.

In the Phase II study,⁴⁵ 143 patients were randomized to one of three groups: treatment with ESL once daily (*n*=50), twice daily (*n*=46), or placebo (*n*=47). In patients treated with the active drug, ESL dose was titrated up to 1,200 mg/d in three steps at 4-week intervals. A statistically significant difference (from the placebo group) in the percentage of responders was noted only for the once-daily group and not for the twice-daily group, and the incidence of adverse events was similar between the treatment groups, with no drug-related serious adverse events occurring. On the basis of these results, ESL has been administered once daily in all other studies.

Main characteristics and results of the three Phase III double-blind, add-on studies are reported in Table 2. In these studies, ESL was started with a dose of 400 or 800 mg once daily, and dose increments to 1,200 mg/d were performed after 1 week or more slowly.

Total duration of the double-blind phase was 12 or 14 weeks.^{46–48} Efficacy end points were proportion of responders (proportion of patients with $\geq 50\%$ decrease in seizure frequency) and the median relative reduction in standardized seizure frequency. Results of these studies have also been pooled.⁴⁹

Overall, results of these studies clearly show that once-daily ESL, at a dose of 800 or 1,200 mg/d, is efficacious and well tolerated as adjunctive therapy in drug-resistant focal epilepsies. Incidentally, in the pooled analysis it was noted that the incidence of AEs was higher in those patients in whom ESL had been added to CBZ.⁴⁹

Two open-label extension studies have been performed^{50,51} as part of the ESL clinical development program in patients who completed registrative Phase III studies.^{46,48} The primary objective of these studies was to evaluate the long-term tolerability and safety of once-daily adjunctive ESL, and the

Table 2 Main characteristics and results of Phase III, double-blind studies performed with eslicarbazepine acetate, in patients with drug-resistant focal epilepsies

Abbreviations: AED, antiepileptic drug; ESL, eslicarbazepine acetate; Pts, patients.

secondary objective was to assess whether the efficacy of this drug was maintained with long-term use.

In these studies the starting dose was once-daily 800 mg for 4 weeks, and, after that, the dosage could be titrated down or up between 400 and 1,200 mg to individualize therapy, while doses of concomitant AEDs had to be kept stable. Of a total of 314 and 325 patients who were enrolled after completing previous double-blind trials,^{46,48} 239 and 223 completed 1 year of open treatment.

Sustained therapeutic effect and favorable tolerability and safety profile were reported in both the long-term studies. Interestingly, in this selected population of patients, the proportion of patients who achieved seizure freedom for a 12-week period ranged between 8.7% and 12.5% for the first study⁵⁰ and 5% and 11% for the second,⁵¹ and improvements in the quality of life and depressive symptoms were observed.

Several recent retrospective studies have confirmed the efficacy and safety of ESL in populations of patients with focal epilepsies of different severity.^{52–55}

Owing to the heterogeneity of casistics and the retrospective nature of these studies, assessments of efficacy could not be done. However, it is confirmed that the tolerability spectrum of ESL is generally favorable. Retention analyses of these heterogeneous studies showed withdrawal rates of 24.6% at 3 months,⁵² of 11.5% at 6 months,⁵³ 27.6% at 1 year,⁵⁴ and 34.9% at 2 years.⁵⁵ In some of these studies, ESL was added to or replaced with CBZ or OXC, and it was noted that switching from OXC to ESL at a dose ratio of 1:1 was apparently associated with a better tolerability during ESL

treatment, while switching from CBZ to ESL did not reduce adverse effects.⁵⁵ It was also noted that ESL efficacy was better in subjects in whom ESL was not coadministered with other sodium channel blockers,⁵⁴ and mainly with LCM.⁵³ All these findings should be taken with extreme caution and should possibly be confirmed by further studies.

The tolerability pattern of ESL may be in part analyzed in registrative, double-blind studies which allow the assessment of frequent, dose-dependent adverse effects. The most often reported adverse events in clinical trials were neurological, with somnolence, dizziness, vertigo, ataxia, abnormal coordination, diplopia, fatigue, headache being the most frequent.⁴⁹

Recently, a network meta-analysis has compared the tolerability of ESL, LCM, and OXC in drug-resistant epilepsies from double-blind, placebo-controlled trials. At high recommended doses, patients treated with OXC withdrew from the experimental treatment significantly more frequently than did patients treated with ESL and LCM. Furthermore, some vestibulo-cerebellar adverse effects (coordination abnormal/ataxia and diplopia) were significantly more frequently observed in patients treated with OXC than in patients treated with LCM and ESL.⁵⁶

Behavioral and psychiatric disturbances (eg, agitation, anxiety, depression, and even suicide ideation) are a frequent complaint in patients with drug-resistant focal epilepsies, which in some cases can be related to pharmacological treatment.⁵⁷ In clinical studies with ESL, the incidence of psychiatric adverse events was low,⁴⁹ and we can expect that ESL, as OXC, may have positive effects in the treatment of

several psychiatric disturbances even though a meta-analysis failed to show a significant effect of OXC in the treatment of bipolar disorders.⁵⁸

With regards idiosyncratic adverse effects, the incidence of rash, which is the most common idiosyncratic reaction with all AEDs,⁵⁹ seems to be low in patients treated with ESL. This adverse effect occurred in approximately 1% in all Phase III ESL studies,^{46–48} while it has been reported to be up to 10% in subjects treated with OXC⁶⁰ and 11% in subjects treated with CBZ.⁶¹

Serious idiosyncratic drug reactions are described with CBZ and, less often, with OXC,⁶² and recently, pharmacogenetic tests have been suggested to prevent the occurrence of serious cutaneous drug reactions in patients starting selected drug therapies.^{63–65} Since eslicarbazepine is the active metabolite of both ESL and OXC, even though reports on severe adverse drug reactions with ESL are still not available, it may be safe to prescribe these tests in selected populations of predisposed patients before starting this drug.⁶⁶

Hyponatremia (defined as sodium level <130 mM/L) during ESL treatment has been observed in 0.6%–1.3% of patients in premarketing clinical trials.^{46–49} In the Elger et al⁴⁶ study, mean sodium levels seemed to have an inverse correlation with ESL dosage. However, in the Ben-Menachem et al⁴⁸ study, three of the four patients with hyponatremia were also taking CBZ. Hyponatremia has also been reported in 1.2% of patients in an open-label, extension study,⁵¹ and its values were reported to change from normal to low in 3.2% of patients in another extension study.⁵² In retrospective studies, hyponatremia has been sporadically reported, but systematic assessments of hematological parameters have not always been performed, and this may have led to underestimation of possible abnormalities.⁵⁵ In the Villanueva et al⁵⁴ study, sodium levels ranging from 116 to 128 mEq/L were reported in nine patients (2.7%), four of whom discontinued treatment. Further studies should assess in more detail the frequency of hyponatremia in patients under treatment with ESL.

Finally, a study specifically aimed at assessing the effect of ESL on the ECG (electrocardiogram) of healthy volunteers failed to show a clinically significant prolongation of the QT interval,⁶⁷ although prolongation of the PR interval has been observed in clinical studies.³² Caution should be exercised in patients with medical conditions (eg, low levels of thyroxine, cardiac conduction abnormalities such as second- and third-degree heart block), or when taking concomitant medicinal products known to be associated with PR prolongation.³²

Experiences in children: efficacy, tolerability, and safety

There is very limited information on the efficacy and safety of ESL in the pediatric population. To date, there is only one published trial that has analyzed the pharmacokinetics, efficacy, and tolerability of this AED in a small pediatric population of drug-resistant patients.³⁶ Doses were from 5 (starting doses) to 30 mg/kg/d. The pattern of tolerability was dose dependent, similar to what has been observed in adults, and the adverse events were characterized by somnolence, diplopia, vomiting, disequilibrium, and dizziness. In this exploratory study, a dose-dependent decrease in seizure frequency was generally observed.

Few adolescents with focal epilepsies have also been treated with ESL in open studies.⁵⁵

A double-blind, placebo-controlled parallel group trial on children aged 2 to less than 18 years with drug-resistant partial-onset seizures has been completed (NCT 00988156, BIA-2093-305) but not yet published.¹³

A low-dose formulation and/or an oral suspension formulation should be made available for pediatric patients in the near future.¹³

Conclusion and future perspectives

Some experimental and clinical findings seem to indicate that in respect to OXC, ESL might share similar efficacy but with a more favorable tolerability profile.

Fluctuations of drug levels in plasma affect susceptibility to some AEs,⁶⁸ as it has been clearly demonstrated with CBZ.⁶⁹ Although much less data are available for OXC, in this case it has been observed that several dose-dependent neurological adverse effects occur intermittently and appear almost always a few hours following drug administration.⁷⁰ Since these adverse effects are time-locked with OXC peak concentration, it seems reasonable to suspect that these are caused by OXC and not by the active metabolite eslicarbazepine, the levels of which increase more slowly.⁴³ These kinetic characteristics are lacking after the administration of ESL, which is directly metabolized to eslicarbazepine.¹¹

Although data from clinical studies do not allow a precise assessment of efficacy,⁷¹ tolerability, as assessed by the percentage of patients with some typical dose-dependent, treatment-emergent, neurological adverse events, has been found to be better than that observed with OXC.⁵⁶ Further studies are needed to confirm this finding.

In future, this agent might be also used in patients with newly diagnosed partial-onset seizures and other neurological

and psychiatric disorders, such as neuropathic pain, migraine, and mania. Indeed, clinical studies aimed at assessing the efficacy of ESL in these fields are ongoing.

Drug Design, Development and Therapy**Dovepress****Publish your work in this journal**

Drug Design, Development and Therapy is an international, peer-reviewed open-access journal that spans the spectrum of drug design and development through to clinical applications. Clinical outcomes, patient safety, and programs for the development and effective, safe, and sustained use of medicines are a feature of the journal, which

has also been accepted for indexing on PubMed Central. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <http://www.dovepress.com/drug-design-development-and-therapy-journal>
