Abstract: The α_2 -adrenergic receptor agonist guanfacine, in its extended-release formulation (GXR), is the most recent nonstimulant medication approved in several countries for the treatment of attention-deficit hyperactivity disorder (ADHD) as monotherapy and as adjunctive pharmacotherapy to stimulants in children and adolescents. The present paper aims to review comprehensively and critically the pharmacodynamic and pharmacokinetic characteristics and the published evidence on the efficacy and safety profile of GXR in the treatment of ADHD. A comprehensive search of relevant databases (PubMed, Embase, and PsycInfo) was conducted to identify studies published in peer-reviewed journals until January 15, 2015. Though the precise mechanism of action of guanfacine in the treatment of ADHD is not fully understood, it is thought to act directly by enhancing noradrenaline functioning via α_{2A} -adrenoceptors in the prefrontal cortex. Weight-adjusted doses should be used, with a dosing regime on a milligram per kilogram basis, starting at doses in the range 0.05–0.08 mg/kg/day, up to 0.12 mg/kg/day. As evidenced in short-term randomized controlled trials and in long-term open-label extension studies, GXR has been shown to be effective as monotherapy in the treatment of ADHD. Furthermore, GXR has also been found to be effective as adjunctive therapy to stimulant medications in patients with suboptimal responses to stimulants. Many of the adverse reactions associated with GXR, particularly sedation-related effects, were dose-related, transient, mild to moderate in severity, and did not interfere with attention or overall efficacy. There are no reports of serious cardiovascular adverse events associated with GXR alone or in combination with psychostimulants.

Keywords: guanfacine extended-release, attention-deficit hyperactivity disorder, ADHD, oppositional symptoms, adjunctive therapy, cardiovascular safety

Introduction

Attention-deficit hyperactivity disorder (ADHD) is a complex, heterogeneous, and highly prevalent neurodevelopmental disorder characterized by a persistent pattern of age-inappropriate symptoms of inattention, hyperactivity, and/or impulsivity.^{1,2} The prevalence of ADHD is approximately 5%–8% in children and 2.5%–4% in adults worldwide.^{1,3,4} Along the life span, ADHD is associated with important personal, medical, and social complications, significant functional impairment, and high rates of associated psychiatric disorders.^{1,5–7} Conduct disorders, including oppositional defiant disorder (ODD), anxiety disorders, and mood disorders, are the most common psychiatric comorbidities in children and adolescents with ADHD.^{1,5,8,9}

ADHD has multifactorial origins, resulting from the complex interaction of biological and environmental risk factors, including multiple genetic factors in conjunction with prenatal events and infant complications.^{10,11} A growing body of evidence reveals

ADHD-related dysfunctions in multiple neuronal networks involved in higher-level cognitive and sensorimotor functions.¹² However, the frontostriatal network, which involves structures like the lateral prefrontal cortex (PFC), dorsal anterior cingulate cortex, caudate nucleus, and putamen, linked with attention, impulsivity, and activity control, appears to be key in understanding the pathophysiology of ADHD.^{13,14}

Since the publication in 1937 of a study showing the therapeutic effects of Bzedrine, the racemic mixture of levo- and dextroamphetamine for hyperactive, inattentive children,¹⁵ stimulants, including amphetamine (AMP) derivatives and methylphenidate (MPH) formulations, have been widely used and remain first-line pharmacotherapies for individuals with ADHD, due to their evidence-based efficacy.^{9,16–18} However, a proportion of patients do not tolerate or fail to respond adequately to stimulants.^{19,20} In addition, some patients or their caregivers prefer not to take stimulant medications, and in some cases there are contraindications to MPH- or AMP-based treatments, including symptomatic cardiovascular disease, glaucoma, or some severe or unstable comorbid psychiatric disorders, as well as concerns about drug diversion.^{9,21,22} Consequently, other safe and effective pharmacotherapies have emerged for treating patients with ADHD. Atomoxetine (ATX; Strattera[®]; Eli Lilly and Company, Indianapolis, IN, USA),²³ a selective noradrenaline-reuptake inhibitor, was the first nonstimulant drug approved for the treatment of ADHD, and in Europe is at present the only medication approved to be used in adult patients with ADHD. More recently, following the results of pivotal, randomized, double-blind, placebo-controlled studies^{24–26} showing the efficacy and good tolerability profile of guanfacine in its extended-release formulation (GXR) in youth diagnosed of ADHD, this α_2 -adrenergic receptor agonist has been approved (Intuniv[®]; Shire PLC, Wayne, Dublin, Ireland) in several countries for the treatment of ADHD as monotherapy and as adjunctive therapy to stimulant medications in children and adolescents (6–17 years of age).

Although some recent reports,^{22,27} including a systematic review and meta-analysis,²⁸ have reviewed the usefulness of GXR in the treatment of ADHD, additional evidence has been published on the efficacy, tolerability, and cost-effectiveness of this α_2 -adrenergic receptor agonist as a pharmacotherapy for ADHD. Therefore, the present paper aims to provide a comprehensive, critical, and updated review on the pharmacodynamic and pharmacokinetic characteristics and published evidence on the efficacy, cost-effectiveness, and safety and tolerability profile of GXR in the treatment – as monotherapy or as an add-on medication – of children and adolescents with ADHD.

Materials and methods

A comprehensive search of relevant databases (PubMed, Embase, and PsycInfo) was conducted to identify potentially relevant studies published in English in peer-reviewed journals until January 15, 2015, using the following search terms: (“guanfacine” or “guanfacine extended-release”) and (“child” or “adolescent” or “pediatrics”) and (“ADHD” or “attention deficit disorder” or “attention hyperactivity disorder” or “hyperactivity” or “hyperkinetic disorder”). The literature search included clinical studies with children or adolescents aged 6–17 years as participants. There were no restrictions on the identification or inclusion of studies in terms of publication status, type of publication, or design type. However, abstracts of presentations to specialist meetings and conferences were not included. Titles and abstracts were screened for inclusion/exclusion and appropriateness, and full-text versions were retrieved.

Pharmacology of guanfacine

Guanfacine is an agonist at α_{2A} -adrenergic receptor distributed in different brain regions, but heavily concentrated in the PFC and the locus coeruleus. In addition to their primary indication as antihypertensive agents, α_2 -adrenergic receptor agonists have been used for a variety of childhood and adult psychiatric disorders, including migraine, Tourette’s syndrome, nicotine dependence, and opiate-withdrawal symptoms, as well as ADHD.^{27,29–32} Guanfacine’s beneficial actions in ADHD are likely to be mediated by its ability to potentiate noradrenaline neurotransmission and strengthen PFC network connections for the regulation of attention, emotion, impulsivity, and behavior through actions at postsynaptic α_2 receptors.³³

Pharmacodynamic profile of guanfacine

Guanfacine is a selective α_{2A} -adrenergic receptor agonist that shares some pharmacological properties with the non-selective α_2 -agonist clonidine, which in an extended-release formulation (Kapvay[®]; Concordia Pharmaceuticals Inc, Bridgetown, Barbados) has also been approved by the US Food and Drug Administration for the treatment of ADHD in children and adolescents as monotherapy or as adjunctive therapy to stimulants.³⁴ However, while clonidine shows high affinity for all three subtypes of α_2 -receptors (A, B, and C), as well as for imidazoline receptors, guanfacine appears to bind more preferentially to postsynaptic α_{2A} -adrenergic receptors, as it has been reported to have 15–20 times-higher affinity for α_{2A} -adrenergic receptors than for the α_{2B} or α_{2C} subtypes.^{32,35} These differences in receptor affinities between both α_2 -adrenergic agonists may help to explain why

guanfacine causes less sedation and dizziness, and is not as potent in decreasing blood pressure (BP) as clonidine.³⁶

Although the precise mechanism of action of guanfacine in the treatment of ADHD is not fully understood, this α_2 -agonist, which has no central nervous system-stimulant properties, is thought to act directly by enhancing noradrenaline functioning via α_{2A} -adrenoceptors in the PFC.^{37,38} There are presynaptic and postsynaptic α_{2A} -adrenergic receptors, but guanfacine appears to act primarily at postsynaptic receptors through inhibition of cyclic adenosine monophosphate, closing hyperpolarization-activated cyclic nucleotide-gated channels modulating synaptic functioning and strengthening PFC-network connectivity, thereby improving PFC cognitive functions.^{37,39} As a result, guanfacine is hypothesized to enhance the signal-to-noise ratio from environmental stimuli, and may improve the ability to focus on a particular stimulus “above the noise” during periods of low arousal, thus improving symptoms associated with ADHD, including working memory, planning, organization, and response inhibition.^{14,35,39}

Pharmacokinetics of guanfacine

GXR tablets contain guanfacine hydrochloride in a matrix tablet formulation that includes polymers and organic acids to provide extended release of the active drug throughout the gastrointestinal tract.^{33,40} GXR is readily absorbed following oral administration, and has linear pharmacokinetics after administration of single 2 mg doses and repeated 2 mg and 4 mg doses in children and adolescents with ADHD.^{27,40,41} While immediate-release guanfacine (GIR) has an oral bioavailability of approximately 80%,⁴² the bioavailability of GXR is 58%.^{22,33} Furthermore, compared with GIR, GXR was associated with a 60% reduction in peak plasma concentration (C_{max}) and a 43% reduction in area under the plasma concentration–time curve (AUC).^{27,33} Conversely, GXR exhibits a time to C_{max} twice as long as GIR, reaching a time to C_{max} 6 hours after GXR dosing compared with 3 hours after dosing with GIR.^{41,43}

The pharmacokinetics of GXR do not seem to change with dose, but are significantly affected by food intake. When administered with a high-fat meal, exposure to guanfacine from GXR is increased significantly, with approximately a 40% increase in AUC and a 75% increase in C_{max} compared to dosing in a fasted state.^{33,40,41} The food effect could be clinically significant, because many of the important adverse effects of GXR occurred in a dose-related or exposure-related manner. Therefore, in order to minimize the risk of adverse events (AEs), GXR should be administered with a light meal or without food.³³ Guanfacine is moderately bound to

plasma protein, with 64%–72% bound to plasma proteins, independent of drug concentration.⁴²

Guanfacine is cleared both by the liver and the kidney. GXR has a long elimination half-life: 14.4 hours in children and 17.9 hours adolescents after a single 2 mg dose.⁴⁰ Guanfacine is metabolized by oxidation to form 3-hydroxy-guanfacine, its main metabolite.⁴² As evidenced in an in vitro study assessing P-glycoprotein substrate properties, it appears that the role of P-glycoprotein in guanfacine transport is at best minor and unlikely to be of clinical relevance in inter-individual variability in response to guanfacine therapy.⁴⁴ The cytochrome P450 (CYP)-3A4 isoenzyme is the primary enzyme involved in the oxidative metabolism of guanfacine.³³ However, while it does not appear to be an inhibitor of the major CYP isoenzymes, guanfacine is a substrate of CYP3A4/5.³³ Concomitant administration with drugs that inhibit CYP3A4/5 activity significantly increased plasma concentrations of guanfacine, potentially increasing the incidence and severity of AEs.^{22,45} Likewise, administration of guanfacine and another medication that induces the CYP3A4 system, like rifampicin, may decrease the C_{max} of guanfacine by more than 50%.⁴⁵ In addition, when guanfacine and valproic acid are administered simultaneously, plasma valproate levels may rise significantly.⁴⁶ However, two small open-label studies conducted with healthy adults revealed that coadministration of GXR and MPH⁴⁷ or lisdexamfetamine⁴⁸ did not result in significant pharmacokinetic drug–drug interactions.

Dosage and administration

GXR is intended for once-daily dosing. Tablets should be swallowed whole and not be crushed, chewed, or split before swallowing, as this would increase the rate of guanfacine release.³³ Tablets should not be administered with high-fat meals.⁴¹ It is recommended that patients commence treatment with a dose of 1 mg per day, thereafter adjusting in weekly increments of no more than 1 mg, depending on clinical response and tolerability.^{24,25,49,50} However, weight-adjusted doses are preferable, by using a dosing regime on a milligram-per-kilogram basis, considering the results from randomized controlled trials (RCTs), starting at doses in the range of 0.05–0.08 mg/kg/day, up to 0.12 mg/kg/day.^{33,49,51,52} Indeed, as reported in an open-label dose-escalation pharmacokinetic evaluation,⁴⁰ with equal doses of GXR, observed guanfacine plasma concentrations were higher in children than in adolescents and adults, presumably due to the lower body weight of children.⁴² Doses above 4 mg/day in children (aged 6–12 years) and above 7 mg/day in adolescents (aged 13–17 years) have not been studied. Likewise, doses above

4 mg/day have not been evaluated as adjunctive medication to stimulants.³³ Treatment discontinuation of GXR should not be done abruptly, but should be tapered in decrements of no greater than 1 mg every 3–7 days, to minimize the risk of transient increases in BP and heart rate (HR).³³

Efficacy of guanfacine extended release for ADHD

A systematic review and meta-analysis of published and unpublished studies indicated that compared with placebo, guanfacine was safe and effective in treating children and adolescents with ADHD.²⁸ This meta-analysis, which included 1,752 patients of pediatric age from seven RCTs with durations of 6–16 weeks, revealed that overall, 694 of 1,177 (59.0%) children or adolescents in the guanfacine group benefited from the treatment compared to 192 of 575 (33.3%) in the placebo group (pooled odds ratio [OR] 3.2).

Efficacy of guanfacine extended release as monotherapy for ADHD

As summarized in Table 1, several multicenter studies have assessed the efficacy of GXR in the treatment of children and adolescents with ADHD as monotherapy in short-term RCTs^{24,25,49,51–53} and long-term extension studies,^{54,55} as well as adjunctive pharmacotherapy in combination with stimulants for those patients who failed to have an adequate response with the latter medication.^{26,50} All the different studies but one relied on changes on changes from baseline in the Attention-Deficit/Hyperactivity Disorder Rating Scale IV (ADHD-RS-IV) as the primary outcome measure, with one exception⁵³ that used the ADHD-RS-IV as secondary outcome measure. Other secondary measures in the different reports included the Before-School Functioning Questionnaire, Conners Global Index – Parent, Conners Parent Rating Scale – revised: short form (CPRS-R:SF), CPRS-R: long form (CPRS-R:LF), Conners Teacher Rating Scale – revised, Clinical Global Impression – improvement (CGI-I), CGI – severity, Parent Global Assessment (PGA), and Child Health Questionnaire – parent form.

Efficacy of GXR for children and adolescents with ADHD in short-term studies

The efficacy of GXR monotherapy was initially assessed in two similarly designed, pivotal placebo-controlled RCTs in children and adolescents with ADHD (Table 1).^{24,25} In these two short-term trials, patients were assigned to receive either GXR 2, 3, or 4 mg (n=345),²⁴ GXR 1, 2, 3, or 4 mg (n=324),²⁵ or placebo. In either study, all treatment groups

Table 1 Summary of randomized, double-blind, placebo-controlled studies of guanfacine extended-release (GXR) monotherapy in children and adolescents with attention-deficit hyperactivity disorder (ADHD)

Study	Study design – RCT	Sample	ADHD diagnosis (subtypes), n (%)	GXR dose	Study duration	Key findings – efficacy
Biederman et al ²⁴	Multicenter (48 centers, USA), fixed-dose escalation study	n=345 (mean age 10.5 years, range 6–17 years) GXR 2 mg: n=87 GXR 3 mg: n=86 GXR 4 mg: n=86 PL: n=86 Male =257 (74.5%)	ADHD-I: 90 (26.1) ADHD-H/I: 7 (2.0) ADHD-C: 248 (71.9)	GXR 2, 3, or 4 mg/day	8 weeks	<ul style="list-style-type: none"> SI in ADHD-RS-IV scores in all groups of children taking GXR (–16.18 with 2 mg, –16.43 with 3 mg, and –18.87 with 4 mg) versus –8.48 for PL. ES: 0.64 (2 mg GXR), 0.66 (3 mg GXR), 0.86 (4 mg GXR). All children taking GXR (versus PL) showed SI in ADHD-H/I and ADHD-I subscales of the ADHD-RS-IV. At end point compared to PL, all groups on GXR showed SI on CGI-I, PGA, CPRS-R:SF, and CTRS-R. Patients taking GXR were more likely to meet the responder criteria (30% decrease in ADHD-RS-IV and CGI-I ≤ 2) over time ($P < 0.05$ for all GXR doses versus PL) from week 3 through study end.
Sallee et al ²⁵	Multicenter (51 sites, USA), dose-ranging study	n=324 (mean age 11 years, range 6–17 years) GXR 1 mg: n=62 GXR 2 mg: n=65 GXR 3 mg: n=65 GXR 4 mg: n=66	ADHD-I: 82 (25.5) ADHD-H/I: 6 (1.9) ADHD-C: 234 (72.7)	GXR 1, 2, 3, or 4 mg/day	9 weeks	<ul style="list-style-type: none"> At end point, all GXR dose groups showed significant decreases in ADHD-RS-IV total scores (mean –19.6) compared with PL (–12.2), with ES 0.43–0.62. Reductions in ADHD-I and ADHD-H/I subscale scores were also significant at all GXR doses compared with PL. Significantly more subjects taking GXR 1, 3, and 4, but not 2 mg, showed clinical improvements in the CGI-I and PGA compared to PL.

Connor et al ⁵³	Multicenter (33 sites, USA), flexible-dose, dose-optimization study	PL: n=66 Male =233 (72.4%) n=214 (mean age 9.4 years, range 6–12 years) GXR: n=136 PL: n=78	ADHD-I: 27 (12.6) ADHD-H/I: 7 (3.3) ADHD-C: 180 (84.1)	GXR 1–4 mg/day	9 weeks	<ul style="list-style-type: none"> Using parental assessments on the CPRS-R, the 1 and 2 mg GXR doses were considered to have a duration of 8 hours; the 3 and 4 mg/day doses had a 12-hour duration. LSMC from baseline in the oppositional subscale of the CPRS-R:L was –10.9 for GXR and –6.8 for PL (ES 0.59, $P<0.001$). LSMC in ADHD-RS-IV total score from baseline was greater for GXR compared to PL (–23.8 versus –11.5, ES 0.92; $P<0.001$).
Kollins et al ⁵¹	Multicenter (nine sites in the USA), dose-optimization, noninferiority study	Male =147 (68.7%) n=178 (mean age 12.6 years, range 6–17 years) GXR: n=121 PL: n=57 Male =124 (69.7%)	ADHD-I: 42 (23.6) ADHD-H/I: 3 (1.7) ADHD-C: 133 (74.7)	GXR 1–3 mg/day	6 weeks	<ul style="list-style-type: none"> Reductions at end point in mean ADHD-RS-IV total scores were significantly greater with GXR (–18.0) than with PL (–11.9) (LSMC 6.3, $P=0.001$). Significantly more subjects taking GXR versus PL showed a CGI-I ≤ 2 (56.8% versus 35.1%, $P=0.007$). GXR treatment did not impair measures of psychomotor functioning or alertness (CRT, SWM, DSST/Coding, and PERMP), compared with PL. Mean changes from baseline to week 8 (visit 10 or last observation carried forward) in ADHD-RS-IV total scores were significant for both GXR-treatment groups combined (GXR all-active –20.0) and separately (GXR-AM –19.8, GXR-PM –20.1) compared with PL (–11.0). Treatment-effect size 0.77 (all-active), 0.75 (GXR-AM), and 0.78 (GXR-PM). Subjects on GXR showed significantly greater reductions in ADHD-H/I and ADHD-I subscale scores compared to PL, regardless of time of GXR administration.
Newcorn et al ⁵²	Multicenter (47 sites, USA and Canada), dose-optimization study	n=333 (mean age 9.1 years, range 6–12 years) GXR-AM: n=107 GXR-PM: n=114 PL: n=112 Male =235 (70.6%)	ADHD-I: 7 (2.1) ADHD-H/I: 6 (1.8) ADHD-C: 320 (96.1)	GXR 1–4 mg/day	8 weeks	<ul style="list-style-type: none"> Mean weight-adjusted optimal dose for GXR was 0.084 (0.03) mg/kg. LSMC in ADHD-RS-IV total score from baseline was greater for GXR and ATX compared to PL (PL-adjusted differences): GXR –8.9, ES 0.76, $P<0.001$; ATX –3.8, ES 0.32, $P<0.05$. Similar differences were reported in ADHD-H/I and ADHD-I subscales of the ADHD-RS-IV. SI was observed in the CGI-I and the WFRS-P learning and school and family domains with GXR and ATX compared to PL. Mean weight-adjusted optimal doses were 0.084 (0.03) mg/kg for GXR and 1.03 (0.21) mg/kg for ATX.
Hervas et al ⁴⁹	Multicenter (58 centers in eleven European countries, the USA, and Canada), dose-optimization study	n=337 (mean age 10.8 years, range 6–17 years) GXR: n=114 ATX: n=112 PL: n=111 Male =249 (73.9%)	ADHD-I: 36 (10.7) ADHD-H/I: 14 (4.1) ADHD-C: 287 (85.2)	GXR: 0.05–0.12 mg/kg/day (6–12 years, 1–4 mg/day; 13–17 years, 1–7 mg/day) ATX: 10–100 mg/day	Children: 4 weeks Adolescents: 7 weeks	<ul style="list-style-type: none"> Mean weight-adjusted optimal dose for GXR was 0.084 (0.03) mg/kg. LSMC in ADHD-RS-IV total score from baseline was greater for GXR and ATX compared to PL (PL-adjusted differences): GXR –8.9, ES 0.76, $P<0.001$; ATX –3.8, ES 0.32, $P<0.05$. Similar differences were reported in ADHD-H/I and ADHD-I subscales of the ADHD-RS-IV. SI was observed in the CGI-I and the WFRS-P learning and school and family domains with GXR and ATX compared to PL. Mean weight-adjusted optimal doses were 0.084 (0.03) mg/kg for GXR and 1.03 (0.21) mg/kg for ATX.

Abbreviations: RCT, randomized controlled trial (double-blind placebo-controlled); PL, placebo; ATX, atomoxetine; GXR-AM, GXR given in the morning; ADHD, Attention-deficit hyperactivity disorder; ADHD-C, ADHD combined subtype (*Diagnostic and Statistical Manual of Mental Disorders [DSM-IV-TR]*); ADHD-H/I, ADHD hyperactive/impulsive subtype (*DSM-IV-TR*); ADHD-I, ADHD inattentive subtype (*DSM-IV-TR*); SI, significant improvement; ES, effect size; LSMC, least-squares mean change; ADHD-RS-IV, ADHD Rating Scale IV; CGI-I, Clinical Global Impression – improvement; CPRS-R:LF, Conners Parent Rating Scale – revised; long form; CPRS-R, Conners Parent Rating Scale – revised; CPRS-R:SF, Conners Parent Rating Scale – revised; short form; CTRS-R, Conners Teacher Rating Scale – revised; PGA, Parent Global Assessment; WFRS-P, Weiss Functional Impairment Rating Scale – parent report; CRT, choice-reaction time; DSST/Coding, Digit Symbol Substitution Task/Coding Test; PERMP, Permanent Product Measurement of Performance; SWM, spatial working memory.

showed significant improvements in ADHD core symptoms, as indicated by significant reductions in ADHD-RS-IV scores at end point compared to placebo, starting 1–2 weeks after they began receiving once-daily GXR, with effect sizes (ESs) ranging from 0.43 to 0.86.^{24,25} Post hoc subgroup analyses revealed that while children 6–12 years of age taking any of the GXR doses in either study exhibited significant improvement compared to placebo, this was not the case for adolescents (aged 13–17 years). Although the small sample size of this cohort in both studies – 23.2% (n=80)²⁴ and 25% (n=80)²⁵ of the total sample – did not allow the drawing of clear conclusions, this finding may support the need, as mentioned earlier, of using weight-adjusted doses.^{33,40} In addition, both studies^{24,25} reported significantly greater mean improvements at end point with GXR compared with placebo on both the inattention and hyperactivity/impulsivity subscales of the ADHD-RS-IV, and on secondary outcome measures, including the CGI-I, the PGA, the CPRS-R:SF and the Conners Teacher Rating Scale – revised.

An additional 9-week RCT explored the effects of GXR (1–3 mg/day, mean weight-adjusted optimal dose 0.052 mg/kg/day) on psychomotor functioning, alertness, and daytime sleepiness in 182 children and adolescents with ADHD using a laboratory-classroom setting (Table 1).⁵¹ GXR was associated with a significant mean reduction in ADHD-RS-IV at end point, and significantly more patients receiving GXR were rated as improved (56.8%) compared to placebo (35.1%). However, there were no significant differences between GXR and placebo on measures of psychomotor functioning, alertness, or other cognitive tasks; likewise, GXR was not associated with increased daytime sleepiness, thus suggesting that the beneficial effects of GXR on ADHD symptoms were independent of sedation-related effects.

The efficacy and tolerability of GXR (up to 4 mg/day) administered in the morning (GXR-AM; mean dose 2.9 mg/day) or in the evening (GXR-PM; mean 3 mg/day) compared to placebo was assessed in another 8-week multicenter RCT with 333 children 6–12 years of age with ADHD (Table 1).⁵² GXR-AM or -PM was associated with significant and clinically meaningful improvements in ADHD symptoms, as evidenced by reductions in ADHD-RS-IV scores compared to placebo, with ESs of 0.75 for GXR-AM and 0.78 for GXR-PM, and onset of efficacy starting at first postbaseline visit.⁵² A post hoc analysis of the data from this dose-optimization study assessed the consistency of the effects on oppositional and ADHD symptoms throughout the day of once-daily GXR-AM or -PM monotherapy using the CPRS-R:SF.⁵⁶ At end point, children taking GXR showed significantly greater improvement from baseline in

mean CPRS-R:SF total score, and in each of the morning, afternoon, and evening CPRS-R:SF assessments compared with placebo, regardless of the time of GXR administration ($P<0.001$). In addition, GXR was associated with significantly greater improvements from baseline in each CPRS-R:SF subscale score (oppositional, cognitive problems/inattention, hyperactivity, and ADHD index) compared to placebo, regardless of time of administration, with ESs within each subscale across the different times of GXR administration ranging from 0.55 to 0.85 for GXR-AM and from 0.47 to 0.68 for GXR-PM.

More recently, Hervas et al⁴⁹ assessed the efficacy and safety of once-daily dose-optimized GXR (0.05–0.12 mg/kg/day: 6–12 years, 1–4 mg/day; 13–17 years, 1–7 mg/day) compared with placebo and ATX (10–100 mg/day) in the treatment of children and adolescents with ADHD. GXR and ATX were significantly more effective than placebo in improving core symptoms, as assessed by changes from baseline in ADHD-RS-IV total score (GXR –23.9, versus ATX –18.8, versus placebo –15.0); in addition, there was a significantly greater reduction in ADHD-RS-IV total score in GXR compared with ATX (–5.1, ES 0.440; $P=0.001$). At end point, significantly more patients taking GXR and ATX compared to placebo showed an improvement in CGI-I (67.9%, 56.3%, and 44.1% for GXR, ATX, and placebo, respectively). Statistically significant differences were seen for other key secondary variable measures, including Weiss Functional Impairment Rating Scale – parent-report learning, school, and family domains in the GXR group compared with placebo. Onset of efficacy was seen at visit 3 (week 1) for GXR and at visit 5 (week 3) for ATX.

GXR for comorbid oppositional symptoms in children with ADHD

Another placebo-controlled RCT explored the effects of GXR monotherapy (1–4 mg daily, mean 2.87 mg/day) on oppositional symptoms in children aged 6–12 years with a diagnosis of ADHD (Table 1).⁵³ Change scores at end point in the oppositional subscale of the CPRS-R:LF from baseline was the primary efficacy measure of this 9-week dose-optimization study. Compared with placebo, treatment with GXR was associated with significantly greater improvements in CPRS-R:LF oppositional subscale scores, with an ES of 0.59. Furthermore, GXR significantly reduced core symptoms of ADHD, as assessed by the clinician-rated ADHD-RS-IV total score, with an ES of 0.92. A post hoc correlation analysis between percentage reduction from baseline to end point in CPRS-R:LF oppositional subscale and ADHD-RS-IV total scores revealed a positive correlation

between reductions in oppositional symptoms and ADHD core symptoms ($r=0.74$).

In order to better characterize the effects of GXR on oppositional symptoms in children diagnosed with ADHD and comorbid ODD, a matching-adjusted indirect comparison explored the efficacy of GXR and ATX in reducing oppositional symptoms in children with this comorbidity.⁵⁷ Data from 143 children with ADHD (6–12 years of age) taking GXR from the 9-week RCT evaluating the effects of GXR on comorbid oppositional symptoms⁵³ were compared with the data from a subset analysis of 98 children aged 7–13 years taking ATX from two identical, 9-week, multisite, double-blind RCTs assessing the safety and efficacy of ATX in ADHD and comorbid ODD.⁵⁸ GXR was associated with a significantly greater reduction in mean CPRS-R:LF oppositional subscale scores compared with ATX (-5.0 versus -2.4 , ES 0.58; $P=0.01$).⁵⁷

Efficacy of GXR for children and adolescents with ADHD in long-term studies

Two open-label studies have assessed the long-term (up to 24 months) safety and efficacy of GXR as monotherapy or in combination with psychostimulants in the treatment of children and adolescents with ADHD.^{54,55} A total of 240 participants participated in the first of the extension studies,⁵⁴ while 259 children 6–17 years of age with ADHD were included in the second long-term open-label extension trial.⁵⁵ Patients were recruited from the two pivotal RCTs,^{24,25} although the second extension trial included a small subgroup of 54 patients from a short-term open-label study of GXR adjunctive to a psychostimulant⁵⁰ as well. In both studies,^{54,55} GXR treatment (to a maximum of 4 mg/day) was associated with sustained, significant improvements in ADHD symptoms, as assessed by ADHD-RS-IV total score. Furthermore, both clinician-rated, based on the CGI-I, and parental-rated, as assessed with the PGA, global assessments revealed that a majority of patients – approximately 60% of the sample in either study – were much or very much improved at end point compared with baseline.^{54,55}

Efficacy of guanfacine extended release as add-on therapy for ADHD

GXR has also been shown to be efficacious as adjunctive therapy to psychostimulant medications, as shown in an open-label safety study⁵⁰ and a large double-blind RCT.²⁶ A multicenter, open-label, 9-week dose-escalation study examined the safety and effectiveness of GXR (1, 2, 3, or 4 mg/day; mean 3.1 mg/day, 0.07 mg/kg/day) administered

concomitantly with MPH or AMP in 75 children and adolescents aged 6–17 years (mean age 11.6 years) with ADHD who had suboptimal control of ADHD symptoms with psychostimulants alone.⁵⁰ Coadministration of GXR and MPH or AMP was generally safe and associated with statistically and clinically significant ADHD-symptom improvement. Indeed, a significant reduction from baseline (psychostimulant alone) in ADHD-RS-IV total score was observed with combination therapy (stimulants + GXR -16.1 [56%], $P<0.0001$; MET + GXR -17.8 , AMP + GXR -13.8); similar significant reductions were observed in mean scores of both the inattentiveness ($P<0.0001$) and hyperactivity/impulsivity ($P<0.0001$) subscales of the ADHD-RS-IV. In addition, 73% and 84.1% of children and adolescents in the study showed an improvement in CGI-I and PGA scores, respectively.

A larger 9-week, multicenter, double-blind, placebo-controlled, dose-optimization study further examined GXR (up to 4 mg/day), either GXR-AM or GXR-PM, as an adjunct to their stable morning long-acting psychostimulant dose in a sample of 461 children and adolescents 6–17 years old (mean age 10.8 years) with suboptimal but partial response to psychostimulant alone.²⁶ GXR-AM or -PM administered adjunctively to MPH or AMP showed significantly greater improvement over placebo plus psychostimulant in ADHD symptoms, as evidenced by reductions in ADHD-RS-IV scores (GXR-AM -4.5 , GXR-PM -5.3), while ESs were 0.38 and 0.45 for the GXR-AM and GXR-PM groups, respectively. Similar significant reductions in the inattentive and the hyperactivity/impulsivity subscale ratings of the ADHD-RS-IV were seen with GXR compared to placebo, regardless of time of GXR administration. A greater percentage of patients taking GXR in combination with psychostimulants met stringent criteria for response, as assessed by $\geq 40\%$ or $\geq 50\%$ reduction from baseline in ADHD-RS-IV total score and remission (ADHD-RS-IV total score ≤ 18) compared with placebo and psychostimulant medication.⁵⁹ Significantly more subjects in both the GXR-AM and GXR-PM groups were judged as improved and to be less severely ill, as measured by CGI-I and CGI – severity scores, respectively, than subjects in the placebo group.²⁶ In addition, participants receiving GXR along with their current stable dose of psychostimulant showed significantly greater improvement at end point on the morning and evening assessments of the Conners Global Index – Parent, as well as on the parent-rated and the participant-rated Before-School Functioning Questionnaire than participants taking placebo and psychostimulants.⁶⁰ Finally, patients receiving GXR plus psychostimulant demonstrated significant reductions on the oppositional subscale of the CPRS-R:LF compared to those

taking placebo plus psychostimulant, both in the overall study population, as well as in the subgroup of subjects with significant baseline oppositional symptoms.⁶¹

Cost-effectiveness of guanfacine for ADHD

ADHD is a costly disease associated with a large economic burden to society and the health care system.^{62,63} However, a growing body of research has shown that pharmacotherapy is cost-effective compared with no treatment or behavioral therapy alone among children and adolescents with ADHD.^{9,64} Furthermore, pharmacotherapy has been found to be cost-effective compared with combined therapy of pharmacotherapy plus behavioral treatment in the overall ADHD population.⁶⁴ With the emergence of several generic formulations of certain stimulant medications and the approval of new pharmacotherapeutic alternatives for the management of ADHD, cost-effectiveness analysis of the different treatment options has become increasingly important in order to provide clinicians and payer decision makers a broader informed decision, particularly in light of the current state of limited health care resources. Recent reports have assessed the cost-effectiveness of GXR as monotherapy compared to ATX,^{65,66} or as an adjunctive to stimulants compared to maintaining existing stimulant monotherapy.⁶⁷

The cost-effectiveness of GXR versus ATX for the treatment of ADHD in children and adolescents was explored using a novel comparative effectiveness method: matching-adjusted indirect comparison.⁶⁵ The study revealed that in the trial-population GXR, within the dosing range of 0.075–0.12 mg/kg/day was more efficacious than ATX 1.2 mg/kg/day, the highest effective dose approved.^{65,66} In addition, the economic value of GXR as an adjunctive pharmacotherapy to stimulants compared with maintaining existing stimulant monotherapy in children and adolescents with ADHD who had a suboptimal response to stimulants alone has been assessed in a cost-effectiveness analysis, with the aim of addressing an unmet need among patients with an inadequate response to stimulant monotherapy.⁶⁷ The results from this economic evaluation showed that the addition of GXR to existing stimulant monotherapy, on average, resulted in 0.028-higher quality-adjusted life-years than stimulants alone, and an incremental cost-effectiveness ratio of US\$ 31,660/quality-adjusted life-year, thus suggesting that GXR is cost-effective as an adjunctive therapy to stimulants compared with stimulant monotherapy for treating ADHD in children and adolescents with a suboptimal response to stimulant medications.⁶⁷

Safety and tolerability of guanfacine

As shown in Table 2, a high proportion of patients in both the active GXR and placebo arms –73.8%–84.2% and 57.7%–75.8%, respectively – experienced treatment-emergent AEs (TEAEs) in the short-term RCT of GXR for ADHD with a cumulative sample of 1,617 children and adolescents (GXR 1,107, placebo 510).^{24,25,49,51–53} The most common TEAEs in these studies associated with GXR compared with placebo were somnolence (27.0%–50.7% versus 3.5%–22.8%), headache (16.7%–26.3% versus 10.6%–24.3%), upper abdominal pain (6.1%–14.3% versus 2.6%–9.1%), fatigue (10.9%–25.4% versus 2.0%–18.0%), and sedation (5.9%–14.5% versus 2.7%–4.5%). Similar rates of TEAEs were detected in long-term extension studies of GXR for ADHD, with somnolence, headache, fatigue, and upper abdominal pain the most common TEAEs.^{54,55} Likewise, a systematic review and meta-analysis of published and unpublished studies reported that compared with placebo, guanfacine was safe and generally well tolerated.²⁸ A total of 948 participants (82.4%) receiving guanfacine and 376 (67.9%) taking placebo experienced at least one TEAE (OR 2.6), somnolence (OR 4.9), sedation (OR 2.8), and fatigue (OR 2.2) the most common TEAEs.²⁸ Many of these adverse reactions, particularly sedation-related TEAEs, were dose-related, transient, mild to moderate in severity, and did not interfere with attention.^{22,27,41} Furthermore, as described earlier, GXR efficacy is seemingly independent of general sedation-related effects.⁵¹

The incidence and severity of TEAEs with adjunctive administration of GXR to a psychostimulant^{26,50} was overall similar to that observed in the clinical studies of GXR alone. Moreover, no unique TEAE emerged from GXR adjunctive to a long-acting psychostimulant.^{26,50} This is consistent with findings from studies conducted in healthy adults showing that no unique TEAEs were observed with coadministration of GXR and MPH⁴⁷ or lisdexamfetamine⁴⁸ compared with either treatment alone.

As expected, discontinuation rates due to TEAEs in the clinic were higher in the groups of children and adolescents receiving GXR than in those on placebo. Indeed, 3.3%–16.2% of patients in the active GXR groups compared to 0%–7.6% in the placebo groups discontinued the study because of TEAEs in short-term RCTs.^{24,25,49,51–53} Likewise, the incidence of discontinuation as a result of TEAEs in studies evaluating the safety and efficacy of GXR as an adjunctive treatment to stimulant medications was 6.6%–6.7% for individuals taking GXR and stimulants^{26,50} and 0.7% for placebo and stimulants.²⁶ In the two long-term extension

Note: Data from the multicenter RCT conducted by Kollins et al¹ were not included in this table, because only the three most common TEAEs were included in their report.

Abbreviations: GXR, guanfacine extended-release; PL, placebo; ATX, atomoxetine; NR, not reported; RCT, randomized controlled trial.

studies, discontinuation rates of GXR as a consequence of TEAEs were 13.5%⁵⁵ and 26.9%.⁵⁴

Cardiovascular safety of GXR

Dose-dependent, small-to-modest reductions in systolic BP (SBP), diastolic BP (DBP), and HR have been observed in GXR-treated patients, as monotherapy or as an add-on to psychostimulants, compared to placebo, approximately -5 mmHg (SBP), -3 mmHg (DBP), and -6 bpm (HR) for all dose groups combined.^{24–26,51} Following long-term treatment with guanfacine, as with other α_2 -adrenergic agonists, tolerance to the hypotensive effects develops, and abrupt withdrawal-rebound hypertension for several weeks may occur.^{22,33,68} Therefore, when tapering off GXR, gradual dose reduction of no more than 1 mg every 3–7 days is recommended.³³

There are no reports of serious cardiovascular AEs, including no serious QTc abnormalities, associated with GXR alone or in combination with psychostimulants in the different multisite studies.^{27,69} Across the different short- and long-term studies assessing the efficacy and safety of GXR for ADHD, minor changes in electrocardiography (ECG) parameters apparently lacking clinical significance have been reported, with no patient presenting a QRS interval ≥ 120 ms, QTc interval ≥ 500 ms (using Fridericia's correction formula, correction QTcF), or QTcF increase from baseline ≥ 60 ms.^{24,25,50,51,53,54} Mean increases in QTcF from baseline in GXR-treated patients across the different RCTs ranged from 6.1–9.1 ms,²⁴ 2.4–9.7 ms,²⁵ 3.3 ms,⁵⁰ and 5.2 ms,⁵³ to -0.1 ms⁵⁴ where detailed QTcF reporting was provided. No “meaningful difference” in QTc intervals were reported in four studies,^{26,49,51,55} and one RCT did not assess QTc intervals.⁵² Similarly, there are no reports of serious cardiovascular AEs when combining GXR and psychostimulant medication. Changes from baseline in QTcF intervals ranged in one of the studies⁵⁰ from 0.01 to 5.15 ms, and no subject met the ECG-outlier criteria (PR interval ≥ 200 ms, QRS interval ≥ 120 ms, QTc interval ≥ 500 ms, or QTc change from baseline ≥ 60 ms). In a large multicenter RCT,²⁶ no subject, regardless of dose and time of administration, developed a QTc ≥ 480 ms (using Fridericia's formula) or QT ≥ 500 ms (using Bazett's formula). These findings from the different trials assessing the efficacy of GXR for ADHD are consistent with a thorough, double-blind, crossover QT study of GIR (at therapeutic [4 mg] and suprathreshold [8 mg] doses) conducted in a sample of 83 healthy adults.⁷⁰ Moreover, as expected, TEAEs were mild, but neither therapeutic nor suprathreshold doses of guanfacine prolonged QTcF interval through 12 hours postdose, thus supporting the view that guanfacine does not

appear to interfere with cardiac repolarization of the form associated with proarrhythmic drugs.⁷⁰

Conclusion

As evidenced in short-term RCTs and in long-term open-label extension studies, GXR administered once daily either in the morning or evening has been shown to be effective as monotherapy in children and adolescents with ADHD.^{24,25,28,49,51–55} Furthermore, GXR has also been associated with significant and clinically meaningful improvements in ADHD symptoms as adjunctive therapy to MPH- or AMP-based medications in patients with suboptimal responses to stimulants.^{26,50} Indeed, the treatment ESs across the different studies are comparable with that observed with other medications used for treating children and adolescents with ADHD.^{23,71} Moreover, GXR may show greater symptom reduction than ATX.^{49,57} The effectiveness of GXR on oppositional symptoms in children with ADHD^{53,56,57} could be of particular interest, based on the high rates of comorbid ODD and ADHD,⁸ but also considering that atypical antipsychotics are widely used, generally in combination, for patients with ODD or other severe comorbidities.⁷² In contrast, the different studies demonstrated a positive risk–benefit profile of GXR in the treatment of children and adolescents with ADHD.^{24–26,28,49–51,53–55} While the incidence of sedation-related AEs is more frequent than with ATX or stimulants,⁵¹ these appear to be unrelated to the therapeutic effects of GXR, and the overall pattern and incidence of TEAEs are consistent with that seen with other medications approved for ADHD.⁷³ Although BP and HR should be monitored prior to initiation of therapy and periodically during guanfacine treatment, ECG monitoring is unnecessary unless there is a personal or family history of cardiac disease, arrhythmias, or sudden unexpected death.^{68,69} Overall, the reviewed evidence suggests that GXR will be a useful and safe nonstimulant treatment option for the broad-spectrum management of ADHD symptoms.

Neuropsychiatric Disease and Treatment

Publish your work in this journal

Neuropsychiatric Disease and Treatment is an international, peer-reviewed journal of clinical therapeutics and pharmacology focusing on concise rapid reporting of clinical or pre-clinical studies on a range of neuropsychiatric and neurological disorders. This journal is indexed on PubMed Central, the 'PsycINFO' database and CAS,

Submit your manuscript here: <http://www.dovepress.com/neuropsychiatric-disease-and-treatment-journal>

Dovepress

and is the official journal of The International Neuropsychiatric Association (INA). The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
