Background: Candida spp. are normal flora of the vagina that eventually become pathogenic under some prevailing conditions, and thus present as a common etiology of vulvovaginitis. When prompt recognition and laboratory confirmation is not achieved, this could lead to devastating genital discomfort and a major reason for frequent hospital visits.

Aims: This was a cross-sectional prospective study that aimed to determine the prevalence and some associated risk factors of vulvovaginal candidiasis (VVC) among nonpregnant women attending University of Abuja Teaching Hospital, Gwagwalada.

Subjects and methods: A pair of high vaginal swab and endocervical swab samples was collected from each of 200 individual participating subjects. They were separately inoculated on Sabouraud’s dextrose agar and incubated aerobically at 33°C for 48 hours. Ten percent KOH wet mount and Gram staining was done on swabs and colonies, respectively. Structured questionnaires were used to obtain sociodemographic and clinical data.

Results: Of the 200 participating subjects, the prevalence of Candida albicans was 6.5% and that of non-albicans candidiasis 7.5%. Candidiasis was observed mostly among the 20- to 30-year age-group. All subjects with Candida-positive culture had been on antibacterial therapy prior to participating in this study – 28 (100%). There was a statistical relationship between the prevalence of VVC with previous antibacterial therapy (P<0.05), but not with age or other prevailing health conditions studied (P>0.05).

Conclusion: The outcome of this study indicated involvement of Candida spp. in vulvovaginitis among nonpregnant women, especially those on empirical antibacterial therapy. Moreover, it is worthwhile to consider culture-test results as adjunctive in combination with clinical symptoms in the definitive diagnosis of VVC. Due to the importance of our findings, sex-education workshops should be conducted to educate women on the clinical significance of Candida in vulvovaginitis.

Keywords: vulvovaginal candidiasis, antibacterial therapy, nonpregnant, Abuja

Introduction

Vulvovaginal candidiasis (VVC) is a fungal or yeast infection of the female lower genital tract, the vulva, and the vagina caused by Candida spp.1–3 It can be referred to as candidiasis or moniliasis. VVC can be recurrent or relapsing.4,5 Recurrent or relapsing VVC occurs when a woman presents with four or more episodes per year. This condition affects less than 5% of healthy women.6

Candida spp. are part of the lower genital tract flora in 20%–50% of healthy asymptomatic women.7 C. albicans is the most frequent colonizer, and is incriminated in most cases of VVC.8 Nevertheless, over the last 10 years, research evidence has demonstrated an increment in the frequency of cases caused by non-albicans species, with C. glabrata...
consistently being the leading species.\textsuperscript{9,10} About 75% of women will experience at least one episode of VVC during their lifetime. In fact, 70%–75% of healthy adult women have at least one episode of VVC during their reproductive life, and half of college women will by the age of 25 years have had one episode of VVC diagnosed by a physician.\textsuperscript{11}

VVC is not considered a sexually transmitted disease, because it does affect children and celibate women, and also Candida spp. are seen as normal vagina flora in healthy women. However, this does not mean that Candida cannot be sexually transmitted.\textsuperscript{12–14}

Diagnosis of VVC based solely on patient history and genital examination is not possible because of the low specificity of symptoms and signs, since other causes mimic VVC, like leukorrhea and pruritus vulvae;\textsuperscript{15} therefore, to have a definitive diagnosis of VVC, cultural isolation and identification of Candida spp. are crucial.

Previous findings have provided data on the incidence of VVC. These suggested that approximately two-thirds of women experience at least one episode during their lifetime, and nearly 50% of women had multiple episodes.\textsuperscript{16,17} It is interesting to note that most previous studies focused on immunocompromised subjects, especially pregnant women, diabetics, subjects on broad-spectrum antibiotic therapy, women on oral contraception with high estrogen content, and HIV-positive subjects, with few studies on otherwise immunocompetent women.\textsuperscript{18}

The normal vagina is characterized by dynamic interrelationships between Lactobacillus acidophilus and other endogenous flora, estrogen, glycogen, vaginal pH, and metabolic by-products of these microbiomes. L. acidophilus produces hydrogen peroxide (as a by-product of metabolism), which is toxic to pathogens and keeps the healthy vaginal pH acidic. Vaginitis occurs when the vaginal microflora have been altered by invading pathogens or biochemical changes in the environment.\textsuperscript{19} Changes in the vaginal environment encourage the Candida population, enhance their adherence to vaginal epithelial cells, and facilitate germination of daughter yeast cells.\textsuperscript{19} These changes may transform asymptomatic colonization into symptomatic Candida infection. VVC, like many vulvar diseases, has the potential to cause great psychological distress and negatively impact a patient’s quality of life.

**Subjects and methods**

**Study area**

This study was conducted at the University of Abuja Teaching Hospital, Gwagwalada, Abuja. Gwagwalada is one of the five local government area councils of the Federal Capital Territory of Nigeria, together with Abaji, Kuje, Bwari, and Kwali; the territory includes the city of Abuja, the capital city of Nigeria, which is located in the center (9°40′N, 7°29′0″E) of Nigeria. Gwagwalada has an area of 1,043 km\(^2\), and had an estimated population of 157,770 at the 2006 census.

**Sample-size calculation**

The sample size was determined using data from a prevalence study conducted in Nigeria with a prevalence of vaginal candidiasis of 14%, as demonstrated by Okonkwo and Umeanaeto.\textsuperscript{20} Therefore, the minimum sample size required for this study with a 5% margin of error and 95% confidence level was 185.

**Study population**

A pair of high vaginal swab (HVS) and endocervical swab (ECS) samples was collected from each of 200 individual participating subjects. Subjects were recruited from the General Out-patient and Gynecology departments at the University of Abuja Teaching Hospital, Gwagwalada. The selection of patients was done with the support of attending physicians and nurses of these departments.

**Criteria**

Inclusion criteria were age between 15 and 45 years, with or without signs and symptoms of vulvovaginal discomfort, and not pregnant. Exclusion criteria were age under 15 or over 45 years, pregnant, diabetics, and menstruating. The procedure employed consisted of a questionnaire interview and the taking of patients’ clinical history.

**Ethical clearance and informed consent**

This study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Human Research Ethical Committee of the University of Abuja Teaching Hospital. All subjects gave their written informed consent for inclusion before they participated in the study. All data were analyzed anonymously throughout the study.

**Questionnaire**

Structured questionnaires were used by attending physicians to obtain such data as age, marital status, prior antibacterial therapy, clinical signs and symptoms, and provisional diagnosis.

**Sample collection**

HVS and ECS specimens were carefully and appropriately collected with sterile cotton swabs from the vagina and
cervix, respectively. While contamination was minimized, a pair of swabs was collected from each subject. Both were separately inoculated onto Sabouraud’s dextrose agar and incubated at 25°C and 37°C respectively, aerobically. Thereafter, 10% KOH wet mounts were made from the swabs and examined microscopically using a 40× objective lens for the presence of pseudohyphae and/or budding yeast cells suggestive of Candida.21

Identification

Yeast growths were identified by characteristic colonial morphology of Candida on Sabouraud’s dextrose agar. Growths were then confirmed to be Gram-positive budding fungal cells by Gram staining. Germ-tube tests were also performed to identify C. albicans.

Statistical methods

Data generated from questionnaires and results of the laboratory analysis were entered into Microsoft Excel and analyzed using SPSS software (version 20; IBM Corporation, Armonk, NY, USA). Results obtained were reduced to percentages, tables, and a figure. The Pearson χ² test at a 95% confidence interval and 0.05 level of significance was used to determine the relationships between some sociodemographic/clinical data and prevalence rates.

Results

This was a 6-month study on VVC among nonpregnant women aged 15–45 years with and without clinical signs and symptoms of vulvovaginal discomfort attending the University of Abuja Teaching Hospital, Gwagwalada for medical assistance and voluntary participation. Paired HVS and ECS samples were collected from each of the 200 participating subjects and analyzed for isolation and identification of both C. albicans and non-albicans Candida spp.

Of the 200 subjects recruited, 28 had Candida-positive cultures from both HVS and ECS samples, making the prevalence of VVC 14.0%. Candida-positive cultures were observed mostly among the age-group 20–30 years (17 [8.5%]) and least among those less than 20 years and greater than 40 years (Table 1). There was no significant statistical relationship between the prevalence of VVC and age (P>0.05).

There were equal Candida-positive cultures among women who presented with clinical symptoms of ill health and those who were apparently healthy and voluntarily came for the study (with no clinical presentations of ill health). Of 83 test subjects who presented with one or more clinical symptoms of ill health, 14 (16.9%) had candidiasis. However, of 117 women who voluntarily participated (those with no clinical symptoms of ill health), 14 (11.9%) had candidiasis. There was no statistically significant relationship between candidiasis and prevailing clinical symptoms of ill health (P=0.34, Table 2). All subjects with Candida-positive culture had been on antibacterial therapy prior to participating in this study, 28 (100%), (Table 3).

Of the 200 participating subjects, only 24 had notable clinical symptoms of vulvovaginal discomfort and seven candidiasis, putting the prevalence at 29.2% (Figure 1). However, the prevalence of C. albicans among the general test subjects was 6.5% (13 of 200), and that of non-albicans candidiasis was 7.5% (15 of 200) (Table 1).

Discussion

Vaginal candidiasis is a common mucosal membrane infection caused predominantly by C. albicans, which can affect significant numbers of otherwise healthy women of childbearing age. Vaginal candidiasis is one of the common infections of general medical practice, second only to anaerobic bacterial vaginosis. About three-quarters of all women suffer at least one episode of this condition during their lifetime.22

The prevalence of vaginal candidiasis reported by different studies was 16.5%, 21.31%, and 19%.22-24 In our study, the prevalence was found to be 14%. This relatively low prevalence of vaginal candidiasis among women attending the University of Abuja Teaching Hospital may be attributed to adequate knowledge, good personal hygiene, and normal levels of estrogens and corticoids.25

Note: χ²=6.0, P-value =0.777.
Candida-positive cultures were observed mostly among the age-group 20–30 years (17 [8.5%]) and least among those less than 20 years and greater than 40 years. These findings are not in consonance with the findings of Alo et al, who reported a higher prevalence of C. albicans (33.33%) within the age bracket of 36–40 years, while those between 20 and 25 years had the lowest prevalence (20.42%). This outcome agreed with Akortha et al and Willacy and Jackson, who reported peak vaginal infec-
tions between ages 20 and 40 years. This may be due to high sexual activity, poor personal hygiene, the use of contraceptives, and drug abuse among this age-group. Those 26–30 years old represent the peak of childbearing in Nigerian societies, and it was among this group that significantly high prevalence of vaginal candidiasis occurred. Advancement in age, on the other hand, reduces the effect of estrogen hormone in women, which could lead to lower infection rates as women advance in age. Most women aged over 46 years have reached menopause and are less or not sexually active. They rarely use contraceptives to prevent pregnancy, and they also seldom misuse drugs. They also have a possible increase in vaginal immunity, as they have decreased levels of estrogen and corticoids, and thus are resistant to Candida infections.

These factors probably contributed to the lowest occurrence rate of vaginal Candida species in this age-group (>40 years). This finding is in line with a previous report by Okungbowa et al, who reported prevalence of 10% and 2% within the age-groups of 36–45 and over 46 years, respectively. They reported that this was probably due to the possible increase in vaginal immunity with age; however, no age-group was absolutely free of vaginal candidiasis.

There was no statistically significant relationship between the prevalence of VVC with age (P>0.05) or prevailing clinical symptoms of ill health (P>0.05). This could have been a result of recurrent infections that might have contributed to resistance of the vagina to candidiasis. This can reduce the chances of isolating the yeast organism.

Subjects with vulvovaginal discomfort had a higher percentage of Candida-positive cultures (29.1%) than those with no vulvovaginal discomfort (11.9%). This report is in agreement with the findings of Jombo et al. It is reasonable to believe that young women with genital discomfort consult health care centers more often than women without such symptoms.

This report revealed the prevalence of C. albicans among general test subjects to be 6.5% (13 of 200), which was slightly lower than that of non-albicans candidiasis (7.5%)

Note: $\chi^2 = 11.44, P$-value <0.05.

[15 of 200]). This finding is in agreement with the findings of Aring et al., who also observed a concomitant increase in the prevalence of non-\( \text{albicans} \) species in their study group. Their study reported that among the non-\( \text{albicans} \) species, \( \text{C. glabrata} \) was the most common type (10.52%) and \( \text{C. krusei} \) the least common type (3.51%). Studies have shown that \( \text{C. glabrata} \) is one of the major causes for recurrent VVC. More than 10% of women in their study were infected with \( \text{C. glabrata} \), which further agrees with Corsello et al. Vaginitis induced by non-\( \text{albicans} \) species is clinically indistinguishable from that caused by \( \text{C. albicans} \). The reason for the increase in incidence of VVC caused by non-\( \text{albicans} \) species is thought to be single-dose antifungal treatment, low-dosage azole-maintenance regimens, and the use of over-the-counter antifungals. Therefore, for effective control of candidiasis, it is advisable to identify the \( \text{Candida} \) spp. alongside clinical symptoms before planning for treatment.

All subjects with positive \( \text{Candida} \)-culture results had already been on antibacterial therapy prior to their hospital visit – 28 (100%). This finding is in conformity with the fact that prolonged antibacterial use usually affects vaginal bacteria microflora population and biochemical activity (mainly \( \text{L. acidophilus} \)), which thus increases vaginal pH as a result of reduced CO\(_2\) production. This feature, alongside other factors (such as hormonal factors), encourages \( \text{Candida} \) overgrowth, consequently leading to vulvovaginitis. Although the widespread use of antibiotics has been suggested as one of the major factors contributing to the rising incidence of VVC, some case-control studies found no evidence of an association between antibiotic agents and symptomatic VCC, whereas others reached the opposite conclusion.

The low prevalence of candidiasis reported from these nonpregnant women could not be extensively discussed with studies from our locality due to paucity of data on similar findings. Most previous studies focused on pregnant women and other immunocompromised subjects. Therefore, there is a need to create awareness of the involvement of \( \text{Candida} \) spp. in genital discomfort, especially vulvovaginitis, among nonpregnant women with or without notable signs and symptoms, in order to avoid unnecessary and empirical antibacterial therapy. More so, it is worthwhile to consider culture-test results as adjunctive in combination with clinical symptoms in the definitive diagnosis of VVC. There is a need to build on findings generated from this study in order to identify/characterize the non-\( \text{albicans} \) \( \text{Candida} \) spp. isolated and possibly conduct antifungal susceptibility testing.

Acknowledgment

We would like to acknowledge the staff of the Medical Laboratory Services, Gynaecology and General Out-patient departments, University of Abuja Teaching Hospital for their technical support and taking part in generating clinical data from subjects.
