Background: Betaine has the potential to spare methionine and choline as methyl-group donors, and is thought to improve broiler performance under conditions of stress. An experiment was conducted to ascertain the effects of supplemental betaine on performances and physiological responses of broilers exposed continuously to thermal stress.

Materials and methods: Male broilers (n=128, divided into four groups, with eight replicate cages in a group) received diets containing suboptimal levels of methionine and metabolizable energy and supplemented with 1.3 g/kg and 2 g/kg betaine hydrochloride from day 1 to 38. The positive control (PC) did not contain supplemental betaine, and the negative control (NC), to which betaine was added, was deficient in methionine and energy and devoid of added choline. The experiment included assessment of growth, feed-conversion ratio, rectal temperature and respiration rates, and assay of blood hormones and metabolites.

Results: Betaine at both the levels of inclusion improved live weight and feed intake over the PC and the NC groups. Rectal temperature and respiration rates were also lower in the betaine-supplemented groups, indicating a sequestering effect of betaine on metabolic rates of thermally stressed broilers. Carcass yield was unaffected. Betaine-supplemented groups had better thyroid activity than the NC and PC groups of birds.

Conclusion: Based on this study, it was inferred that in tropical countries betaine may be effectively used to ameliorate the negative impact of high ambient temperature in broiler chickens. The findings also suggest that at an appropriate dose, betaine may spare some quantity of DL-methionine and dietary energy to support the growth process of heat-stressed broilers. However, further studies are warranted to assign a definite methionine and energy matrix to supplemental betaine that can be used in broiler diets without inviting any risk of drop in production.

Keywords: betaine, broiler chickens, heat stress, performance, physiological responses

Introduction

Combating heat stress remains a challenge for the broiler industry in the tropics, and efforts are under way to develop dietary measures that can ameliorate heat stress to achieve optimum performance. Exposure to high ambient temperature causes serious physiological dysfunctions and triggers secretion of corticosteroids, which being catabolic in nature severely depress animal performance.^{1,2} The term “stress” is commonly used to describe the detrimental effects of a variety of situations on the health and performance of poultry, and may be defined as the set of responses to external demands that call upon the flocks to adapt to a new and an abnormal situation.³ This adaptation process releases hormones and redistributes nutrient reserves at the cost of performance.⁴⁻⁶ The thermoneutral zone for poultry is 18°C–24°C in the tropics

and 12°C–26°C in the temperate zones, but this often gets exceeded in the tropics, resulting in heat stress.^{7,8} By elevating circulatory corticosteroids and decreasing thyroid activity, heat stress impairs broiler performance, especially in adult birds, because the ability to dissipate heat decreases with age.^{9,10} Drastic decline in feed intake occurs in heat-stressed birds as a physiological response to minimize intrinsic heat production and to maintain the thermal homeostasis, thus bringing down feed efficiency, live weight gain, and survival rates.^{11–14} Lower breast-meat yield and higher carcass-fat deposition are the other deleterious effects of heat stress that lower the economic value of broiler carcasses.^{10,11,15}

Betaine, the trimethyl derivative of the amino acid glycine, is a naturally occurring compound distributed widely in many plants and animal tissues.¹⁶ Betaine has multiple functions that include donation of its labile methyl group, which is used in transmethylation reactions for synthesis of carnitine and creatine.^{17,18} Dietary supplementation of betaine presumably reduces the requirement for other methyl-group donors, such as methionine and choline.¹⁹ As a feed additive, betaine is most commonly added to animal diets as anhydrous betaine, betaine monohydrate, and betaine hydrochloride.^{17,18} Betaine hydrochloride is a chemically synthesized product containing trimethylamine (TMA). It has been a matter of apprehension that the widely varying TMA content in betaine HCl may pose some risk for chickens being fed on diets containing betaine HCl. However, the European Food Safety Authority indicated that for meat- and egg-purpose chickens, the safe level of dietary TMA and its salt is as high as 2 mg/kg body weight (15 mg/kg feed) and 3 mg/kg body weight (24 mg/kg feed), respectively, which provides enough safety margin for inclusion of betaine HCl in poultry diets.²⁰ Within the body, betaine is synthesized from choline.^{21,22} Being a methyl-group donor, betaine is thought to spare methionine from this function, thus allowing methionine to be utilized more for growth and muscle development.²³ Choline presumably alleviates heat stress in broilers due to its ability to be oxidized readily to betaine, which is then used as a methyl-group donor to synthesize methionine. Therefore, both betaine and choline are considered to be potential methyl-group donors, and are hypothesized to spare methionine, at least partially, particularly in conditions where dietary methionine is limited to some extent.²⁴

The present experiment was conducted with broilers exposed continuously to high temperature and humidity. It was hypothesized that being a methyl donor, betaine should compensate for methionine functions as a methyl-group donor in situations where methionine is deficient in diets.²⁵

It was also hypothesized that betaine may be capable of sparing choline altogether, and may conserve the energy consumed in the process of the conversion of choline into betaine. The experimental diets did not contain any added choline, and were suboptimal in methionine. Although the available literature suggests that methionine may be spared by betaine, the exact amount of methionine that can be replaced with betaine is not available. Also, to our knowledge, there are no data available on the energy-sparing effect of betaine. The present study attempted to derive a methionine and energy matrix of betaine hydrochloride in heat-stressed broilers. The objective was to gauge the performance and physiological responses of thermally stressed broilers fed diets containing suboptimal levels of methionine and metabolizable energy and supplemented with different levels of betaine hydrochloride, and to corroborate these responses with some metabolic indices in blood.

Materials and methods

Bird husbandry and experimental diets

The trial was conducted according to institutional ethical norms. One-day-old male Cobb 400 chicks (n=128) were used in a 38-day feeding trial. There were four dietary treatments, and each treatment had eight replicate cages with four birds in each cage. The cages were kept in an experimental room that was artificially illuminated and had provision for ventilation and heating. Each cage measured 0.3×0.3 m, with feeders and drinkers fitted outside. Immediately after receipt, the chicks were weighed individually and put inside the cage, where they could get access to the designated treatment diets instantly. Assignment of chicks into the cages was done following a completely randomized design, so that cage-related variation in performance could be minimized as far as possible. Dark periods of 2 hours and 4 hours per day were maintained during days 1–16 and 17–38, respectively. The birds were vaccinated against the Newcastle disease (live attenuated strain) on days 7 and 20 and the infectious bursal disease on day 14. The temperature of the experimental room varied between 28°C (night) to 35°C (day). Electrical heaters were used intermittently to increase and maintain the constancy in temperature. Maximum and minimum temperatures and relative humidity (RH) in the experimental room were measured using a thermohygrometer at 7 am, 2 pm, and 7 pm every day.

As outlined in the objectives, the experimental diets were formulated with suboptimal levels of methionine and metabolizable energy. Based on the available literature, it was presumed that betaine would be capable of sparing

800 mg of digestible methionine per kilogram of the diet. An energy matrix of 200 KJ/kg was assigned to betaine as well. Therefore, the experimental diets were: 1) a positive control (PC) without any supplemental betaine and formulated according to industry standards; 2) a negative control (NC), which was devoid of any added choline chloride, deficient in metabolizable energy by 200 KJ/kg, and the quantity of added DL-methionine decreased by 33% in both the starter and grower diets; 3) Bet 1.3, which was similar to NC and was supplemented with 1.3 g betaine HCl/kg; and 4) Bet 2.0, which was similar to the NC diet and was supplemented with 2.0 g betaine HCl/kg. Feed and water

was offered ad libitum. The starter (days 1–16) and grower mash (days 17–38) (Table 1) were analyzed for dry matter (heating at 105°C for 16–18 hours), ash (combustion at 550°C to constant weight), crude protein as nitrogen $\times 6.25$ (by the semimicro-Kjeldahl method; Kjeltec Auto System; Tecator AB, Höganäs, Sweden), and lipid (diethyl ether extraction in a Fossfec analyzer [Tecator] after HCl hydrolysis).

Measurements

Live weight gain, feed intake, and feed-conversion ratio (FCR; intake:live weight gain) were calculated cage-wise for each period (days 1–16, 17–38) and for the overall

Abbreviations: PC, positive control; NC, negative control; Bet 1.3, supplemented with 1.3 g/kg betaine hydrochloride; Bet 2.0, supplemented with 2 g/kg betaine hydrochloride.

(days 1–38) period. All birds were slaughtered on day 38 following a 12-hour fast. The birds were mechanically stunted followed by exsanguination. The carcass was then scalded, plucked, and eviscerated. Carcass yield corresponded to carcass weight without shanks, head, neck, wings, viscera, or giblets. Yield of the breast, legs, and back were recorded and expressed as a percentage of live weight.

Deep-body temperature was measured at 12 pm on days 14, 21, 28 and 35 using a digital thermometer (accuracy $\pm 0.1^\circ\text{C}$) inserted approximately 5 cm deep into the rectum. Respiratory rates were measured by counting the panting breaths of a bird for 30 seconds, and this value was multiplied by two to obtain the number of breaths per minute.

Blood samples for metabolite and hormone assays were collected on day 38 after a 12-hour fast. Approximately 5 mL of whole blood was collected from jugular veins into Vacutainer tubes without any anticoagulant. The tubes were kept in ice immediately after collection for an hour for separation of serum. The cells were further separated by centrifugation at $2,500\times g$ for 10 minutes, and the serum was preserved at -20°C till analyzed. A commercial kit was used to estimate serum CO_2 (Biosino Bio-Technology and Services Inc., Changping, People's Republic of China [PRC]), and the test was based on the principle that phosphoenolpyruvate reacts with the bicarbonate present in serum to form oxaloacetate, which then reacts with and oxidizes an $\text{NADH} + \text{H}^+$ analog in the presence of malate dehydrogenase. The reduction in the concentration of the $\text{NADH} + \text{H}^+$ analog, which was proportional to the concentration of CO_2 in blood, was measured photometrically to interpret the results. Serum triacylglycerol was estimated by a commercial kit (Diasis Diagnostik Sistemler, Istanbul, Turkey) in a semiautomatic blood-biochemistry analyzer (RT-9200; Rayto Life and Analytical Sciences Co Ltd, Shenzhen, PRC). Concentrations of triiodothyronine (T_3), thyroid-stimulating hormone (TSH), and corticosterone were determined by enzyme-linked immunoassays with commercial kits (United Biotech Inc., Sunnyvale, CA, USA). All tests were performed in duplicate, and results with intra-assay variations exceeding 5% were rejected.

Statistical analyses

Means and standard deviations were calculated for all quantitative data using the cages as the experimental units, and the treated and control groups were compared using a one-way analysis of variance (ANOVA), with the exception of body weight, rectal temperature, and respiration-rate data, which were compared using a two-way repeated-measure

ANOVA. The primary data analysis was done with SPSS version 17.0 (SPSS Inc., Chicago, IL, USA). When the results of ANOVAs were statistically significant, a Tukey's test for multiple comparisons was performed to compare results of all groups. When variances were significantly different by Bartlett's test, groups were compared using a nonparametric method (Kruskal–Wallis nonparametric ANOVA). The critical value for significance of all comparisons was $P < 0.05$. To estimate the dose response of betaine HCl, polynomial contrasts were applied when a significant mean difference was obtained, and the values are expressed as linear and quadratic responses.

Results

The ingredients and chemical composition of the experimental diets are presented in Table 1. Metabolizable energy in both the starter and grower diets was lower by 200 KJ/kg in the NC, Bet 1.3, and Bet 2.0 groups compared with the PC. The other constituents, including the amino acids except methionine, were similar in all the diets.

The mean temperature in the experimental room was close to the values recommended for Cobb broiler chickens only up to the second week of age. The mean daytime temperature measured at 2 pm was always higher than the standard, and as the experiment progressed, the difference between the suggested and the observed temperature widened (Figure 1). The RH in the experimental room (Figure 2) was 29%–44% higher than that suggested for Cobb broilers.

Rectal temperature (Figure 3) was similar across the diets at day 14 ($P > 0.05$) and higher at days 21 and 28 in the PC and NC groups compared to that in the Bet 1.3 and Bet 2.0 groups ($P < 0.05$). The NC group had a lower rectal temperature than the PC group till day 28, and unlike the PC group, where the temperature increased steeply, the rise in temperature was

Figure 1 Experimental room temperature ($^\circ\text{C}$) measured at different time points in a day.

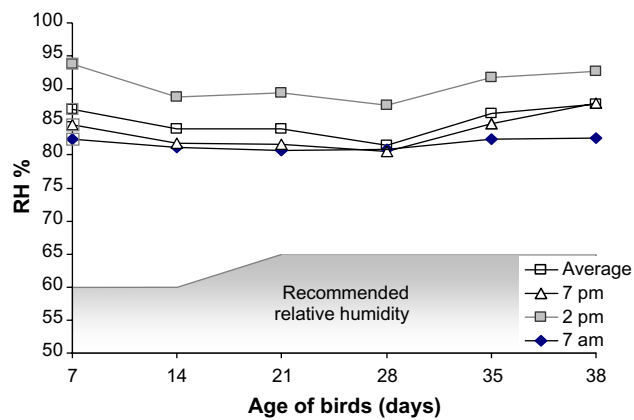

Figure 2 Relative humidity (RH; %) in the experimental room measured at different time points in a day.

more gradual in the former. Rectal temperature in the PC and NC groups started declining after 28 days of age, and at the time of the final measurement (day 35) the difference between the groups was minimal. The respiration rate (Figure 4) in the different dietary groups was in accord with the rectal temperature, and was higher in the PC and NC groups than both the betaine-supplemented groups, particularly at days 21 and 28. In the PC and NC groups, the respiration rate dipped after day 28 and at day 35, the difference between the dietary groups was insignificant. In the Bet 1.3 group, respiration showed an increasing trend during days 21–35, and in the Bet 2.0 group the respiration rate was on a downward trend during days 28–35. Panting occurred in all groups during

Notes: Means of eight replicate cages in each treatment ($n=4$ birds in each cage); *rectal temperature was significantly lower ($P<0.05$) in the Bet 1.3 and Bet 2.0 groups compared with the PC and NC groups at 21 and 28 days of age.

Abbreviations: PC, positive control (diet contained 2.7 g/kg DL-methionine and 1 g/kg choline chloride [60%]); NC, negative control (diet contained 1.8 g/kg DL-methionine and no added choline chloride); Bet 1.3, NC + 1.3 g/kg betaine HCL; Bet 2.0, NC + 2.0 g betaine HCL.

Figure 4 Variation in respiration rate (breaths/minute) of experimental broilers fed diets containing different levels of methionine, choline, and betaine hydrochloride and exposed to thermal stress.

Notes: Means of eight replicate cages in each treatment ($n=4$ birds in each cage); *respiration rate was significantly lower ($P<0.05$) in the Bet 1.3 and 2.0 groups compared with the other dietary groups at 21 days of age, and at 28 days of age the Bet 2.0 group showed a lower ($P<0.05$) respiration rate than the rest of the dietary groups.

Abbreviations: PC, positive control (diet contained 2.7 g/kg DL-methionine and 1 g/kg choline chloride [60%]); NC, negative control (diet contained 1.8 g/kg DL-methionine and no added choline chloride); Bet 1.3, NC + 1.3 g/kg betaine HCL; Bet 2.0, NC + 2.0 g betaine HCL.

the day, when both ambient temperature and RH were on the higher side. The intensity of panting declined at night, when ambient temperature decreased.

Performance data presented in Table 2 indicate that across the diets, live weight at day 16 was better in the Bet 2.0 group ($P<0.001$). Betaine at both levels of inclusion improved feed intake ($P<0.001$) compared with the NC group. There was a quadratic effect of supplemental betaine on FCR, which caused a poorer FCR in the Bet 1.3 group compared with the rest of the treatments ($P<0.05$). During 17–38 days of age, neither feed intake nor FCR was affected by dietary betaine supplementation. However, the birds supplemented with 1.3 g betaine HCL/kg feed gained more body weight compared to those in the PC, NC, and Bet 2.0 groups ($P<0.05$). The effect of supplemental betaine was found to be quadratic ($P<0.05$), and the birds in the Bet 1.3 group gained more body weight than those in the Bet 2.0 group. Overall (days 1–38), the birds in both betaine-supplemented groups had better body weight and body-weight gain ($P<0.05$), and the level of betaine in the diet exerted a linear effect on these parameters ($P<0.05$). Feed intake during days 1–38 improved linearly with the dose of supplemental betaine ($P<0.001$). The FCR was similar across the groups ($P>0.05$). There was no mortality during days 1–16, but during days 17–38 some mortality occurred in the NC and Bet 1.3 groups, taking the overall livability values to 100%, 96.9%, 93.8%, and 100% respectively in the PC, NC, Bet 1.3, and Bet 2.0 groups.

Notes: Means bearing dissimilar letters in superscript varied significantly (* $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$); ^dmeans of eight replicate cages in each treatment (n=4 birds in each cage); ^{a,b,c}Significant differences. ^Llinear effect; ^Qquadratic effect.

Abbreviations: PC, positive control (diet contained 2.7 g/kg DL-methionine and 1 g/kg choline chloride [60%]); NC, negative control (diet contained 1.8 g/kg DL-methionine and no added choline chloride); Bet 1.3, NC + 1.3 g/kg betaine HCL; Bet 2.0, NC + 2.0 g betaine HCL; FCR, feed-conversion ratio; NS, not significant.

Carcass traits were unaffected by diets (Table 3). However, there was a linear effect of the dietary level of betaine on dressed carcass weight ($P < 0.05$), which was 3.74% and 8.18% higher in the Bet 1.3 and Bet 2.0 groups, respectively, compared to the PC.

Betaine supplementation had conspicuous effects on serum biochemical traits and hormonal parameters (Table 4). Serum CO₂ was lower in the NC and the Bet 2.0 groups than the PC and the Bet 1.3 groups ($P < 0.01$). Dietary betaine level had a quadratic effect on serum CO₂ concentration, and the Bet 1.3 group showed higher serum CO₂ levels than the Bet 2.0 group ($P < 0.01$). Betaine at 2.0 g/kg decreased ($P < 0.01$) serum triacylglycerol compared with the other dietary groups, and this response was linear with the inclusion level of betaine in diet ($P < 0.01$). Betaine supplementation linearly increased the concentration of T₃ and TSH in serum ($P < 0.001$), and across the diets T₃ and TSH concentrations were higher in the Bet 2.0 group ($P < 0.001$). Serum corticosterone was lower in the NC group compared with the rest of the dietary

treatments ($P < 0.01$), and supplemental betaine had little effect on this parameter ($P > 0.05$).

Discussion

Rectal temperature and respiration rate of the experimental broilers revealed that the condition of the experimental room exerted sufficient thermal stress on them. Differences between the observed and recommended room temperatures at days 21, 28, 35, and 38 were 21%, 37%, 58%, and 73%, respectively. A high RH aggravated the stress further, and the impact was perhaps more in the younger chickens, because the difference between the observed and the suggested values were wider up to day 21. It was this thermal stress that did not allow the birds in all the treatment groups to achieve the standard body weight, an observation that has already been reported.^{26,27}

Rectal temperature suggested that betaine supplementation at both the dose levels blunted the heat-stress response after day 21, while the PC group of birds could manage this stress only after 28 days of age. Rectal temperature may be

Abbreviations: PC, positive control (diet contained 2.7 g/kg DL-methionine and 1 g/kg choline chloride [60%]); NC, negative control (diet contained 1.8 g/kg DL-methionine and no added choline chloride); Bet 1.3, NC + 1.3 g/kg betaine HCL; Bet 2.0, NC + 2.0 g betaine HCL; T₃, triiodothyronine; NS, not significant.

considered one of the indicators of metabolic rate in broilers, and increases when birds are exposed to high ambient temperature. Betaine supplementation reportedly helps in reducing body temperature to some extent.^{27,28} A lower rectal temperature in the NC group up to day 28 may be explained by a retarded metabolic rate in that group caused by sub-optimal levels of dietary methionine and energy. This also helps in explaining the retarded growth rate in this group. Contrary to the general tendency of the broilers, the birds in the NC group did not attempt to increase feed intake in order to compensate for the deficient nutrients in diets like methionine and energy.²⁹ Probably, the stress was too severe for the birds to respond to by increasing feed intake. Chickens' ability to regulate body temperature during the posthatch period increases with age through neural and hormonal interactions and through epigenetic adaptations.^{30,31} In the early posthatch period, chicks behave more as a poikilotherm than a homeotherm up to 10 days of age, and it is believed that exposure to heat stress at this early period of life makes the chicken more heat-tolerant during the final rearing period, when endogenous heat production is high due to the high metabolic rate.^{31–33} The current findings partially corroborated this hypothesis, since it was observed in this study that rectal temperature in the PC groups started declining at a later age after a steep initial rise.

One of the key indicators of heat stress is a decline in feed intake by about 1% for each 1°C increase in temperature from the bird's comfort zone, and this decline may be as high as 30% at an ambient temperature of 32°C.³⁴ It was observed that under situations of constant temperatures of 25°C and 35°C and a cycling temperature of 30°C–40°C, feed intake and growth rate of broilers decreased by 15.9% and 12.3%, respectively, at 35°C and by 14.9% and 12.5%, respectively, under cyclical heat stress compared to those at 25°C. In the present experiment also, feed intake was severely depressed,

and compared to the breed standard, feed intake was lower by 21% in the NC group and 17% in the PC group at 16 days. Betaine supplementation alleviated the stress partially, since the depression in feed intake in both the betaine-supplemented groups was less than that in the PC and NC groups, and the variation with the breed standard was between 12% and 14%. This was in agreement with earlier observations indicating beneficial effects of betaine supplementation in thermally stressed broiler chickens.^{21,35,36} However, during days 17–38, there was a subtle effect of supplemental betaine on feed consumption, indicating little effect of betaine on feed intake in older birds.^{37,38} Nevertheless, unlike some earlier reports, betaine supplementation at both the dose levels improved feed intake in this study.^{21,39,40} Live weight improved by more than 3% over the PC and NC groups in the Bet 2.0 group, which suggests that at this level of inclusion betaine not only compensated for methionine but also contributed a substantial amount of energy to support this growth process. Feed conversion also improved over the PC group by 3.6 and 4.5 points, respectively, in the Bet 1.3 and Bet 2.0 groups. This improvement in FCR are of substantial commercial value, especially in regions where broilers are reared in open housing systems and thus are exposed to extremes of temperature. Unlike many other experiments evaluating the effects of betaine in broilers exposed to cyclical heat stress, in the current study the birds were exposed to critical thermal stress from the beginning till the end of the trial. Therefore, the impact of the stress and the effect of supplemental betaine might be quite different from other studies.

Serum CO₂ is a measure of metabolic activities of birds, and its higher concentration in the blood suggests greater metabolic activity and may be considered as an indicator of panting. A negative correlation between cloacal temperature and blood CO₂ levels has been reported.⁴¹ Respiratory frequency and evaporative water loss through panting are

linearly related, and they increase with ambient temperature above the panting threshold.⁴² Panting is an energy-consuming response in a hot environment, reduces retention of metabolizable energy, and affects growth.⁴³ When the respiration rate and serum CO₂ levels were correlated, it appeared that betaine at 2 g/kg feed decreased panting. Also, at this level of inclusion, betaine alleviated thermal stress to a greater extent, which was not possible with the lower dose. This was evidenced from a lower respiration rate but higher serum CO₂ level in the Bet 1.3 group. The level of serum CO₂ correlated well with the trend observed with the cloacal temperature over the period of time in all the groups except the NC. However, the patterns of rectal temperature, respiration rate, and body-weight gain in the NC group were indicative of a lower metabolic rate, and may explain the lower serum CO₂ level in this group.

Serum triacylglycerol decreased when betaine was supplemented at a rate of 2 g/kg feed, but not at 1.3 g/kg feed. Reports in this regard are scarce, and most of the available literature indicates little effect of supplemental betaine on serum triacylglycerol.^{38,44} However, betaine supplementation may decrease serum triacylglycerol concentration due to the fact that the hormone-sensitive lipase activity, which catabolizes triacylglycerol to yield energy, decreases with betaine supplementation.^{40,45}

Betaine supplementation elevated serum levels of T₃ and TSH, albeit with a different dose response. The activity of thyroid hormones is negatively correlated with ambient temperature, and at high ambient temperatures the activity of thyroid hormones declines to depress performance of birds. Based on the relationship of thyroid secretion rate to growth demonstrated in chickens, it is possible that the poorer performance in the control group of birds was due partly to the decreased T₃ activity.^{46,47}

High level of corticosteroids in the blood is one of the indicators of stress in broilers.⁴⁸ Thermal stresses induce release of corticotropin-releasing hormone and synthesis of corticosteroids, which ensure the maintenance of homeostasis and recovery from stress.⁴⁹ In laying hens reared under moderately high environmental temperature (maximum 27°C), betaine supplementation (0.7 and 1.5 g/kg) reduced plasma corticosteroid,⁵⁰ which might have been due to the positive effect of betaine on nitric oxide production, which in turn might inhibit the biosynthesis of glucocorticoid.^{51,52} However, in the present study, betaine supplementation did not influence serum corticosterone level. This suggests that betaine elicited its stress-alleviation effect not via the corticosterone-mediated pathway.

The present investigation suggests that betaine can replace all of the added choline from the dietary regimen of heat-stressed broiler chickens with little negative impact on performance. The methionine-sparing effect of choline was not studied, since the role of choline in this regard is questionable.²⁴ The ability of betaine to spare the methionine need of broiler chickens is subject to substantial controversy, and generally it is agreed that supplemental betaine may improve broiler performance only in conditions of stress in broilers that are fed with diets containing suboptimal levels of methionine.^{24,53–55} Betaine supplements in diets deficient in methionine reportedly improved digestibility of starch, and when challenged with coccidia, improved digestibility was observed for other nutrients also.⁵⁴ It is argued that for betaine to elicit any discernible effect, a minimum level of methionine should be present in the diet, and this level may vary between 15 and 20 mg methionine per kilogram of diet.^{55–57} However, all these studies were conducted with natural betaine. The current study added to the existing pool of knowledge by revealing the fact that a similar response may be obtained with betaine HCl too, although a higher dose of 2 g/kg may be required to obtain a desired level of performance.

Conclusion

Based on these data, it was concluded that like natural betaine, synthetic betaine HCL (2 g/kg diet) may be used as a tool to improve performance of broilers under thermal stress conditions. Supplementation of betaine HCl supported the metabolic processes of the birds exposed to thermal stress and thus sustained a better growth rate. Partial removal of added DL-methionine and total removal of choline was found not to have any discernible negative effect on live weight and FCR. Therefore, on the basis of the present data, it may be concluded that supplementation of broiler diets with betaine hydrochloride may successfully ameliorate the negative impacts of thermal stress in broilers. Also, it may be possible to assign some methionine and energy matrix to supplemental betaine, considering the methionine- and energy-sparing effects of betaine obtained in this study, which may be used effectively as a tool in the process of least-cost feed formulation.
