Etiology of cardiovascular disease in patients with schizophrenia: current perspectives

Abstract: Cardiovascular morbidity and mortality are important problems among patients with schizophrenia. A wide spectrum of reasons, ranging from genes to the environment, are held responsible for causing the cardiovascular risk factors that may lead to shortening the life expectancy of patients with schizophrenia. Here, we have summarized the etiologic issues related with the cardiovascular risk factors in schizophrenia. First, we focused on heritable factors associated with cardiovascular disease and schizophrenia by mentioning studies about genetics–epigenetics, in the first-episode or drug-naïve patients. In this context, the association and candidate gene studies about metabolic disturbances in schizophrenia are reviewed, and the lack of the effects of epigenetic/posttranscriptional factors such as microRNAs is mentioned. Increased rates of type 2 diabetes mellitus and disrupted metabolic parameters in schizophrenia are forcing clinicians to struggle with metabolic syndrome parameters and related issues, which are also the underlying causes for the risk of having cardiometabolic and cardiovascular etiology. Second, we summarized the findings of metabolic syndrome-related entities and discussed the influence of the illness itself, antipsychotic drug treatment, and the possible disadvantageous lifestyle on the occurrence of metabolic syndrome (MetS) or diabetes mellitus. Third, we emphasized on the risk factors of sudden cardiac death in patients with schizophrenia. We reviewed the findings on the arrhythmias such as QT prolongation, which is a risk factor for Torsade de Pointes and sudden cardiac death or P-wave prolongation that is a risk factor for atrial fibrillation. For example, the use of antipsychotics is an important reason for the prolongation of QT and some other cardiac autonomic dysfunctions. Additionally, we discussed relatively rare issues such as myocarditis and cardiomyopathy, which are important for prognosis in schizophrenia that may have originated from the use of antipsychotic medication. In conclusion, we considered that the studies and awareness about physical needs of patients with schizophrenia are increasing. It seems logical to increase cooperation and shared care between the different health care professionals to screen and treat cardiovascular disease (CVD)-risk factors, MetS, and diabetes in patients with psychiatric disorders, because some risk factors of MetS or CVD are avoidable or at least modifiable to decrease high mortality in schizophrenia. We suggested that future research should focus on conducting an integrated system of studies based on a holistic biopsychosocial evaluation. Keywords: antipsychotic, cardiovascular risk, MetS, miRNA, QTc, schizophrenia

Introduction

Cardiovascular death is a major contributor to the increased mortality rate (two- to threefold) and to the decreased life expectancy of 20% in schizophrenia victims according to normal population.¹⁻³ The causes for increasing the mortality rate in schizophrenia victims are mostly similar to those in the general population with metabolic syndrome and diabetes mellitus. In addition, some disease-specific risk factors may also contribute to the increasing mortality rate such as follows: being genetically liable or having overlapping genes between cardiovascular disease, sudden cardiac
death and schizophrenia. Requiring antipsychotic drugs and outcomes of such drugs, lifestyle due to negative symptoms, smoking, and alcohol abuse, and inability to obtain good medical care or inability to reach qualitative medical opportunities might also add some risks. In this review, we conducted a retrospective database study to assess the primary potential risk factors of cardiac mortality in first-episode and chronic patients with schizophrenia in light of recent findings in the literature.

Methods
We conducted a systematic search for potentially relevant articles published between the year 1995 and 2015. Our search strategy was to assess the studies in earlier stages of schizophrenia including first-episode psychosis/schizophrenia, first-degree relatives, schizophrenia and cardiac mortality (single nucleotide polymorphisms or microRNA (miRNA) or modifiable risk factors or sudden death or QTc, or P-wave, Torsade de Pointes [TdP]), and glucose or insulin or cholesterol or triglycerides, or blood pressure or weight using health-related databases such as MEDLINE (via PubMed), Embase, and PsycINFO. We have focused on risk factors for mortality and we included systematic reviews, meta-analyses, and studies. We did not attempt to identify unpublished work or search in non-English-written journals.

Findings about genetic and epigenetic mechanisms
The increase in cardiovascular risk factors has also been revealed in antipsychotic naive first-episode patients, before antipsychotic drug invention in the 1920s and even in their healthy relatives. Thus, one may consider whether some common candidate genes are present or not between schizophrenia and cardiovascular risk-prone victims (Table 1).

Atypical antipsychotic-related weight gain was revealed to be associated with INSIG2, or the interaction of INSIG2 with INSIG1. The same investigators detected a significant association between rs498177 single nucleotide polymorphism (SNP) in the serotonin 5-HT2C receptor gene and metabolic syndrome only in female patients with schizophrenia. An association was shown between the endothelial nitric oxide synthetase (eNOS) T-786C genetic variant and endothelial functioning, which was no longer detectable if patients met the criteria of metabolic syndrome.

Besides possible cardiovascular outcomes, in a genome-wide association study (GWAS), common SNPs in the cardiomyopathy-associated gene (CMYA5) were also accused for

Results
- Ac-risk allele in TCF7L2 (rs79031146) was associated with schizophrenia
- Strong association between weight gain and rs17587100, rs1049064A, and rs17047764 localized near INSIG2 gene
- The INSG1 and INSG2 interactions with more frequent in patients with MetS were significant
- Association between eNOS T786C and worse endothelial function (artery tonometry) were assessed

Note: Data are presented as mean ± standard deviation. Abbreviations: SNP, single nucleotide polymorphism; eNOS, endothelial nitric oxide synthetase; MetS, metabolic syndrome.
schizophrenia. Some authors have revealed an association between rs10503929 within the NRG1 gene and sudden unexpected deaths due to ventricular fibrillation in schizophrenia victims. In a five-drug-specific GWAS, genome-wide significance was detected with SNP rs4959235 at SLC22A23 which mediated the effects of quetiapine on QTc prolongation in patients from the Clinical Antipsychotic Trial of Intervention Effectiveness (CATIE) study (Table 2).

miRNAs are small noncoding RNAs that bind to the 30-UTR (untranslated region) of usually many messenger RNAs. Through multiple mechanisms affecting transcription and translation, miRNAs are among the key regulators of posttranscriptional gene expression. In a systematic review, different alterations among miRNA were reported in the postmortem brains of schizophrenia patients. Perkins et al have investigated alterations of miRNAs in 179 rats treated with haloperidol and detected increments of miR-199a, miR-128a, and miR-128b. On the contrary, the downregulation of miR-31 and miR-342-5p was shown in peripheral blood mononuclear cells in vivo in schizophrenia patients. In a recent study, for the first time, the alteration of miRNAs after olanzapine has been found to be associated with metabolic pathway via pathway analysis in mice.

Findings on cardiometabolic risk factors

Data from the general population estimated five metabolic risk factors for predisposition to cardiovascular disease (CVD) approximately twofold increase and to diabetes approximately three- to fourfold increase and widely shaped as: abdominal obesity, elevated triglycerides, reduced high density lipoprotein (HDL) cholesterol, high blood pressure, and elevated fasting blood glucose levels.

In a systematic review of 25 studies in which the average follow-up duration was 31.7 weeks (from January 1990 to June 15, 2010), no difference in metabolic syndrome (MetS) was detected in drug-naïve patients than healthy controls. On the contrary, some authors had found a higher waist/hip ratio and more visceral fat in first-episode patients with schizophrenia than controls although inadequate control matching was an important limitation of these studies. The European First Episode Schizophrenia Trial (EUFEST) was a 1-year open label study in which first-episode (<2 years) or partially antipsychotic naïve patients were recruited. Partially antipsychotic naïve was defined as the use of any antipsychotic drug <2 weeks in the previous year or <6 week antipsychotic treatment at any time including haloperidol, amisulpride, ziprasidone, quetiapine and olanzapine. In that study, the baseline rate of MetS was similar in the drug-naïve and brief antipsychotic use groups and in the general population in Europe (Table 3). Interestingly, 58.5% of the patients have shown individual risk factors for one or more elevated metabolic risks at the baseline as following: 28.5% suboptimal HDL, 24.2% hypertension, 17.7% hyper-triglyceridemia, 8.2% abdominal obesity, and 7.3% hyperglycemia. A meta-analysis was performed with 126 valid analyses from 77 published studies (n=25,692) and data from 14 of these 77 studies (n=800) were included for analysis which had examined first-episode psychosis and/or

drug-naïve patients. Although no comparison with general population was detected within all these 14 studies, the MetS rate was established to be 11.3% (95% CI = 7.3%–16.1%)27 that was surprisingly lower, while the estimated prevalence of the MetS rate in Europe was 18%–20%28 and 25% in the general population in the USA.29

It is commonly accepted that the prevalence of MetS in patients with chronic schizophrenia is higher than that in the normal population. In the CATIE study, the rate of MetS in schizophrenia was found to be 40.9% vs 23.7% in controls (for males 36.0% vs 19.7%; for females 51.6% vs 25.1%).20 In the aforementioned meta-analysis (126 analyses from 77 published studies, n=25,692), the overall rate of MetS was 32.5% (34.8% in males and 34.8% in females). Additionally, MetS was present in 39.2% of older patients with a mean age of 50 years or above27 which shows that the MetS rate is rising with aging in patients with schizophrenia (Table 4).

The overall findings according to this meta-analysis were as follows: the rate of being overweight was 49.4% (N=53) and 44.4% (N=8) according to two different criteria of waist circumference measurement. Hyperglycemia was detected in 19.5% of patients (N=147, n=13,784), while increased triglyceride was 39.3% (N=77, n=19,831), decreased HDL was 42.6% (N=76, n=19,280), high blood pressure was 38.7% (N=72, n=18,657), and presence of diabetes was 10.9% (N=14, n=2,186).31 In addition, the rate of diabetes was reported as being 16% in females and 11% in males with schizophrenia, and only 3% in controls,31 or reported to be 2.5–3-fold higher in the 1990s even before the extensive presence of atypical antipsychotics on the counter.32

In the EUFEST study, the patients had a significantly greater weight gain and increased waist circumference in amisulpride and haloperidol groups than the ziprasidone group at weeks 26, 39, and 52, while no significant change
was detected with respect to weight gain between groups at the first visit. Besides, weight gain and waist circumference were significantly higher at each time-point in the olanzapine and quetiapine groups than in the ziprasidone group.

In this study, no significant changes were seen between antipsychotic trial groups with respect to the blood levels of glucose, total cholesterol, triglyceride, and HDL. However, in a systematic review of FEP trials, the influences of antipsychotic drugs were tested in 25 studies in which the average follow-up time across was 31.7 weeks (ranged from 4 weeks to 2.5 years). Significant changes were common at the sixth month with regard to the total body weight, HDL, low density lipoprotein (LDL), triglycerides, fasting glucose and insulin levels. In this review, the weight gain in olanzapine (5–6 kg) was significantly higher than risperidone (4 kg), and haloperidol (3 kg) at weeks 6–8, while the difference between olanzapine and risperidone was waned at weeks 12–16 (7–9 kg vs 6 kg, respectively). The weight gain did not differ for 1 year across olanzapine, risperidone, clozapine, amisulpride, quetiapine fumarate, and haloperidol. Interestingly, a question was raised as to whether orally disintegrating tablets may have lesser effects on weight gain or not than standard tablets (Table 4).

Although the number of hyperglycemia cases had increased after 52 weeks in the first episode of psychosis Comparison of Atypicals in First Episode of Psychosis (CAFÉ) study and small amounts of increases in the blood glucose level was noted in the EUFEST study small amounts of increases in the blood glucose level was noted in the EUFEST study, no difference was informer between various first- and second-generation antipsychotics. Risperidone was related to the smallest elevations of the triglyceride level in fasting and the smallest reduction in the HDL level than the other comparators such as olanzapine and quetiapine in the CAFÉ study.

The pathophysiology of the underlying MetS is not clear due to antipsychotic use, and an increased risk of CVD cannot be exactly attributed to antipsychotics or sociodemographical aspects of patients with schizophrenia. In a Sweden study, the MetS rate was higher in chronic patients treated with clozapine. In CATIE study (n=689), at the time of assessment, the groups were as follows: 24.8% were drug free/naïve, 58.4% were taking an atypical antipsychotic, 11.9% were under conventional antipsychotic treatment, and 5.0% were taking a combination of antipsychotics. It was found that diabetes mellitus and hypertension and a significantly lower HDL level was significantly more frequent in patients with schizophrenia than that in controls.

In the seminal meta-analysis of Mitchell et al (N=112 studies and n=24,892 patients), 35.3% frequency of MetS in all schizophrenia patients and a 39.2% frequency of MetS in older patients (N=14, n=6,396) have been reported. According to this meta-analysis, using Adult Treatment Panel III criteria, only three drug monotherapy comparisons were possible: the MetS rate was 51.9% (N=13, n=673) for clozapine; 28.2% (N=12, n=1,056) for olanzapine; and 27.9% (N=9, n=659) for risperidone. However, the finding of clozapine in this meta-analysis might have confounders as old age and a longer duration of illness.

### Findings on cardiomyopathic risk factors and sudden cardiac death

In 1899, Emil Kraepelin mentioned extensive autonomic alterations in patients with schizophrenia, such as increased heart rates, altered pupillary function, increased sweating and salivation, and body temperature changes; these described signs suggest increased sympathetic output, decreased parasympathetic modulation, or both.

**Abbreviations:** ECG, electrocardiogram; RRV, RR interval variability; QTV, heart beat-corrected QT interval; FEP, first-episode psychosis; h, hour; IM, intramuscular; HRV, heart rate variability; QTV, QT interval variability; QT, QT interval.
In the last 2 decades, the compromised autonomic system in schizophrenia patients and in first-degree relatives of patients with schizophrenia has been accused for a number of cardiac abnormalities (Table 5). Autonomic dysfunction is most likely the consequence of long-lasting stressful experiences associated with the psychotic state, in addition to a genetic underlying predisposition to autonomic dysfunction as observed in the relatives of patients. For example, decreased RR interval variability (RRV), which is a marker for cardiac parasympathetic activity, has been reported to predict potential fatal ventricular tachycardia. Depression with psychotic features in a Finnish study has also been suggested as a risk factor for sudden death and other arrhythmic events. Jindal et al concluded that drug-naïve patients with first-episode psychosis may have an impaired cardiac autonomic function.

In a meta-analysis study, antipsychotics were reported to increase risk by two- to sixfold for ventricular arrhythmias, sudden cardiac death, and lengthening of heart rate-corrected QT interval (QTc), and it has been widely accepted as a marker of predicting drug-associated cardiac events although no clear evidence for the QT interval prolongation (>500 ms) is related with increased risk for TdP—an increased risk of ventricular tachyarrhythmia or sudden cardiac death. Some questions rise whether there is any difference between atypical and typical antipsychotic drugs in the literature. In a recently published study, no meaningful changes after ziprasidone use was detected in 27 first-episode psychosis (illness duration of <3 years, previous antipsychotic exposure lasting for <2 consecutive weeks).

Indeed, the prolonged QT interval was detected in 8%–23% of patients under antipsychotics treatment and in 2% of healthy controls, while a dose-dependent correlation between the risk of QT lengthening effects and antipsychotic use has also been emphasized.

In a meta-analysis study of seven atypicals (aripiprazole, amisulpride, sertindole, risperidone, quetiapine, olanzapine, and ziprasidone), the authors have collected data of 16 randomized controlled trials (RCTs) from 42 RCTs. They have found that aripiprazole was the only atypical drug that shows both significantly smaller mean change in QTc (P=0.03) and significantly lower risk to cause QTc prolongation (P=0.04), while sertindole was informed with a significant QTc prolongation (P<0.0001). In another study, the QTc interval prolongation effects were ranked as: thioridazine > ziprasidone > quetiapine > risperidone > olanzapine > haloperidol. One of the main questions was sex differences, because it is well-known that females are more prone to QT prolongation as found in a study that the mean QTc interval was shorter in males (391±31 ms vs 400±37 ms, P<0.001). In a recent study according to the mean QTc interval, the results were as follows: quetiapine > olanzapine but quetiapine > risperidone and aripiprazole, and olanzapine > risperidone (Table 6). However, in this study,

**Abbreviations:** OLZ, olanzapine; RIS, risperidone; QTP, quetiapine QT interval; ECG, electrocardiogram; QTc, heart beat-corrected QT interval; TdP, Torsade de Pointes; ECT, electroconvulsive therapy; ms, milliseconds; ARP, aripiprazole; QT, QT interval.
the mean chlorpromazine equivalent doses of olanzapine
and quetiapine were significantly higher than risperidone
and aripiprazole groups. In this study, the average QTc
in females was significantly longer only in the olanzapine
group. However, in a few studies, no sex difference in QTc
was demonstrated in various antipsychotic use such as depot,
atypical, or typicals.

Although there are extensive studies on QTc, very few
studies have emphasized on the PR interval in the literature.
In fact, prolongation of the PR interval might lead to atrial
fibrillation, pacemaker indication, and mortality.
Emul et al have not found a difference on PR after intramuscular
ziprasidone administration while a significantly increased
PR interval after the third electroconvulsive therapy (ECT)
session was reported in patients with schizophrenia who were
under antipsychotic polypharmacy treatment or olanzapine
is accounted for PR prolongation in a recent study.

**Findings about sudden death due
to cardiomyopathy related with
antipsychotic drug use in schizophrenia**

In the literature, a widely accepted etiologic factor for car-
diomyopathy is the use of clozapine. In a 11-year follow-up
study, clozapine was found to be related with the lowest
mortality rate and the fewest number of deaths due to
ischemic cardiac disease than the most frequently used typi-
cal and atypical antipsychotic drugs. Previously, the rate of
clozapine-related cardiomyopathy had been considered to be
similar to that within the normal population (8.9/100,000) in
the USA. Now, the rate of clozapine-induced cardiomyopa-
thy is demonstrated to be five times more frequent than that
in the normal population. In a study after 10 years from the
first described clozapine-induced cardiomyopathy, Reinders
et al estimated the prevalence to be 9.6%. This relatively high
rate may be the real rate of clozapine-related cardiomyopathy
because of the increase in the awareness of the clinicians.
In case reports, usually myocarditis initiates within the
first month of clozapine administration, independent from
dosing with tachycardia, shortness of breath, cough, and
fatigue symptoms in which 12.5%–24% may have mortal
outcomes. In the literature, there are few individual case
reports on cardiomyopathy due to antipsychotic use such as
amisulpride, after quetiapine (n=3), haloperidol, and risperidone.

**Discussion**

Similar to schizophrenia, metabolic syndrome and cardio-
vascular symptoms in schizophrenia are also multifactorial
and associated with the influences of multiple genes in
combination with environmental factors. NRG1 is a signal-

ing protein that mediates cell–cell interactions, which is a
shared development process in schizophrenia and cardiac
function. Interestingly, the minor allele of the non-synony-
mous SNP rs10503929 within the NRG1 gene was associated
with sudden cardiac deaths. Functional polymorphisms
in cytochrome P450, which play important roles in the
metabolism of antipsychotic drugs, might be associated with
prolongation of QTc. The SLC22A23 gene expression is in
the development of heart and SNPs in that the gene might be
related with QT prolongation in some antipsychotics. How-
ever, there are some debates in genetic studies which were
searching for the association of SNPs with schizophrenia: an
association of polymorphism with schizophrenia might be a
chance of observation, replication of the SNP findings are
almost infrequent, the detected SNPs that are not specific to
schizophrenia may also be involved in bipolar disorder, etc,
in a relatively small sample size under psychiatric conditions
(few hundreds to few thousands in GWAS vs >50,000 dia-
betes/cardiac studies). Thus, to boost the power of the associ-
ated SNPs in GWASs, some innovative statistical approaches
are considered in recent studies aiming to neglect the need
of larger and larger samples for detecting cardiovascular risk
factors in schizophrenia, although the richest findings
from GWAS may still have very limited power to predict
the genetic variation in schizophrenia.

In the last decade, a new window is opened after the
discovery of the role of miRNAs to molecular pathology
of schizophrenia with related implication for metabolic
syndrome, being the target of antipsychotic drugs and inter-
action of neurotransmitters including serotonin–dopamine–
glutamate. Changes in miRNA expression levels may
reflect schizophrenia-related issues, conditions of high-risk
individuals/first-episode psychotic, and/or intermediate
targets of antipsychotic drug action that may lead to MetS,
diabetes, and/or sudden cardiac death that are lacking in the
literature. In addition, there are still no clinical and very few
preclinical studies in association with miRNAs and after
antipsychotic drug use. Thus, clarifying the potential role
of miRNA in the pathophysiology of cardiovascular risks in
schizophrenia might lead to the discovery of new therapeu-
tic agents such as agonist miRNA (agomiR) or antagonist
miRNA (antagomiR).

To clarify the related risk factors for increased MetS in
patients with schizophrenia, drug-naïve patients or those who
are at the very beginning stage of the illness and treatment
seems crucial. In the literature, the findings seem far away
from a consistent conclusion about glucose tolerance or insulin resistance in first-episode and/or drug-naïve patients. In addition, there is no consensus about the inclusion criteria of the first-episode psychosis/schizophrenia. Usually, the first-episode studies do not prolong >1 year and high dropout rates in longer trials are major concerns. Meanwhile, inconclusive findings as impaired/non-impaired glucose tolerance or insulin resistance/no effect can be seen in the literature about first-episode and/or drug-naïve patients. However, a question rises about the slightly higher waist/hip ratio at the initial phase just prior to antipsychotic drugs that justify to be investigated. Thus, we considered that the prevalence of MetS rate is not increased at the very beginning of the illness as prior to antipsychotic use that may give opportunity to clinicians for earlier interventions regarding prevention of cardiometabolic events. In addition to waist size, the duration of illness was found to be an important predictor for MetS in schizophrenia in a large-scale meta-analysis study in 2013.

Naturally, patients with first-episode psychosis are more frequently males than females, and females might be more liable to the metabolic side-effects of antipsychotic drugs and to the increment of waist circumference. Questionably, the antipsychotic drug use is increasing and reached top-selling drugs, surpassing lipid regulators or pump inhibitors in the USA in 2008. Although, the pathophysiology underlying MetS due to antipsychotic use is not clear, there are reasons to assume that treatment effects are related to the risk factors for cardiovascular problems. Interestingly, the studies about the influences of antipsychotics on cardiovascular problems do not exceed 1 year and patients who are compliant beyond 1 year might be underestimated. It is important to consider that individuals with schizophrenia may have a disadvantageous lifestyle that may lead to additional reasons for the development of MetS such as substance abuse, stress, inadequate self-care and unavailability of health care, financial problems, smoking, poor diet, low mobility, and lack of exercise, which are beyond this review.

According to the literature, to rank each antipsychotic for QTc prolongation risk seems difficult. Furthermore, the clinical significance for QT prolongation is unclear while QTc >450 ms or >30 ms prolongation of QTc versus baseline is widely accepted as important. Nevertheless, there are few studies investigating cardiac autonomic dysfunction prior to antipsychotic use or after introducing antipsychotic drugs in patients with first-episode psychosis in the literature. There is no reported case of TdP in therapeutic doses of antipsychotics except overdose conditions in the literature. Furthermore, the relation between atypical or typical antipsychotics and sudden cardiac death was questioned after Ray et al’s published registry-based study that had reported similar rates of sudden deaths between atypical and typical drugs. However, this study is considerably criticized because of the definition of sudden death and inattentiveness for deaths due to secondary coronary-cardiometabolic side effects. In general, atypical antipsychotics were thought to be safer than typical ones among the QTc interval or sudden deaths. Although the possible mechanism in the sex difference in the QTc interval among various antipsychotics remains unclear, the serum testosterone level is accused for QTc interval differences. However, in a few studies, no sex difference in QTc was demonstrated in various antipsychotic use such as depot, atypical, or typical, thus there might be some other determinants of QTc changes such as age (particularly, >60 years), drug interactions, and serum electrolytes (ie, hypokalemia or hypomagnesemia). Therefore, some new assessments might be conducted to determine the influences of antipsychotic drugs such as fragmented QRS or the T-wave peak to T-wave end (TpTe) interval and TpTe/QT, which have been accepted as predictors of ventricular arrhythmia more than QTc. In addition, the influence of antipsychotics on atrial conduction is very limited that may be observed on the PR interval or P-wave dispersion.

In the literature, a widely accepted etiologic factor for cardiomyopathy is the use of clozapine. The clozapine-induced immunoglobulin E (IgE)-mediated hypersensitivity reaction, hyper-eosinophilic syndrome with direct cardiotoxic effects of eosinophils through the blockade of the cholinergic M2 receptor, and importantly, increase in noradrenal in after clozapine use than other antipsychotics were accounted for the clozapine-induced cardiomyopathy. In the literature, there are few individual case reports on cardiomyopathy due to other antipsychotics.

**Conclusion**

The studies and awareness about the physical needs of patients with schizophrenia are increasing, which had been neglected for a long time. The health care authorities or organizations are inviting physicians for increased cooperation and shared care between the different health care professionals to screen and treat CVD-risk factors, MetS, and diabetes in patients with psychiatric disorders because some risk factors of MetS or CVD are avoidable or at least modifiable to decrease high mortality in schizophrenia. These outcomes are reinforcing the importance of assessing all patients for cardiometabolic risk prior to and throughout treatment, choosing best fitting
antipsychotics, and monitoring cardiometabolic adverse effects. Thus, aiming to realize this serious challenge, further understanding of the underlying mechanisms and improved CVD prevention and treatment are needed. Finally, these future research groups should focus on conducting an integrated system of studies based on a holistic biopsychosocial evaluation.
