Management of pemphigus vulgaris: challenges and solutions

Abstract: The main objective in the treatment of pemphigus vulgaris is to control the disease, prevent relapses, and avoid adverse events associated with the prolonged use of steroids and immunosuppressive agents. Systemic corticosteroids remain the gold standard treatment for pemphigus vulgaris. Azathioprine and mycophenolate mofetil are the first line of steroid-sparing treatment. Rituximab is extremely effective in recalcitrant pemphigus, when other treatments fail to control the disease. The European Dermatology Forum recommends tapering prednisolone by 25% every 2 weeks after the consolidation phase, and a 5 mg reduction every 4 weeks when the dose is reduced to <20 mg. If the patient relapses, options include increasing steroids back to the previous dose, adding an immunosuppressant if using steroid monotherapy, or replacing a first-line immunosuppressant by another if already on combination therapy.

Pemphigus vulgaris: treatment challenges

Pemphigus vulgaris (PV) is a potentially fatal autoimmune, intraepithelial disease characterized by flaccid blisters and erosions of the skin and mucous membranes and histologically by acantholysis.1 It is mediated by circulating desmoglein-reactive autoantibodies directed against keratinocyte cell surfaces.2

The primary objective of the therapeutic management of PV is initially to control the disease, heal the bullous skin and mucous lesions, and minimize the associated functional impairment. Subsequently, the real challenge is to prevent relapses in the long run and avoid adverse events associated with the prolonged use of steroids and immunosuppressive agents. Such intent requires close clinical monitoring of efficacy and safety of treatment.3 The rapid tapering of steroids once control of the disease has been achieved and the introduction of novel immunosuppressants with less long-term adverse events have decreased both morbidity and mortality of pemphigus patients in the last decades.4 However, there are still unmet needs in pemphigus therapy. Even though medical literature highlights the pivotal significance of tapering the immunosuppressive treatment, there are few guidelines on the duration of maintenance therapy or the prerequisites of discontinuation. The objective should be to achieve as rapid a remission as possible, as few flare-ups as possible, and minimal morbidity associated with treatment agents. The challenge is to minimize hospitalization and improve patients’ quality of life.

PV is characterized by diversity that makes every patient a unique challenge. Patients might present with lesions solely on mucous membranes and have limited cutaneous or extensive mucocutaneous involvement. Comorbidities such as diabetes mellitus, hypertension, previous or existent malignancies, chronic infections, and associated...
Complications might limit available treatment options. In addition, treating patients during the onset of the disease is quite different than treating patients with recalcitrant disease or patients after multiple remissions, since the latter usually have more compromised health-related quality of life and compliance with treatment. This diversity in patient population along with the rarity of the disease is the main reason for the limited number of comparative studies in pemphigus treatment. There are many therapeutic interventions in use that have not been evaluated in well-designed randomized controlled trials (RCTs). Sample sizes of conducted trials are often small and have been occasionally evaluated as insufficient to yield definitive results.\textsuperscript{3} Most published data regard patients during disease onset. Duration of follow-up also varies in the literature, limiting the capacity to conduct long-term risk-benefit analysis. Lack of uniform outcome measures limits the possibility of meta-analysis and the strength of evidence-based treatment guidelines. An effort has been made to introduce common definitions and end points in PV treatment by the European Dermatology Forum (EDF)\textsuperscript{3} and a recent international consensus.\textsuperscript{6} In addition, development of severity scores for the disease will help in comparative evaluation of different trials. Evaluation of mild, moderate, or severe disease differs among experts. Some authors define severity on the basis of body surface area affected, while others use the number of new blisters per day to delineate between limited and severe disease.\textsuperscript{7–9} However, even in the absence of new blisters and regardless of affected areas, the involvement of functional critical sites such as mucosal surfaces or ocular disease may require more aggressive therapy.

Common definitions, end points, and severity scores mean that even data from underpowered trials can be used in conjunction with other similar ones in a meta-analysis. The purpose of this review is not to provide a detailed evaluation of all treatment options in PV. We will focus on controversial issues in the use of the most common agents and how to stand up to the treatment challenges based on literature evidence when available.

**Consensus statement**

The consensus statement of mutually acceptable common definitions for pemphigus was developed by the International Pemphigus Committee.\textsuperscript{6}

Baseline is defined as the day that therapy is started by a physician.

Control of disease activity is the time from baseline to the time at which new lesions cease to form and established lesions begin to heal. This marks the beginning of the consolidation phase.

End of consolidation phase is defined as the time at which no new lesions have developed for a minimum of 2 weeks and approximately 80% of established lesions have healed. Clinicians start to taper corticosteroids (CSs).

Complete remission on therapy is defined as the absence of new or established lesions for at least 2 months while the patient is receiving minimal therapy.

Minimal therapy is defined as \( \leq 10 \) mg/d prednisolone (or equivalent) and/or minimal adjuvant therapy for at least 2 months.

Minimal adjuvant therapy is defined as half of the dose required to be defined as treatment failure.

Complete remission off therapy is defined as the absence of new and/or established lesions for at least 2 months while the patient is off all systemic therapy for at least 2 months.

Relapse/flare is the appearance of \( \geq 3 \) new lesions/month that do not heal spontaneously within 1 week, or by the extension of established lesions, in a patient who has achieved control of disease activity.

One could argue that such definitions are more suitable in a clinical study environment. However, they can easily be implemented even in everyday hospital clinical practice without complicated calculations, and offer an invaluable common evaluation of each patient in every treatment stage.

**Treatment agents**

The aim of pharmacologic therapy for PV is to reduce inflammatory response and autoantibody production.

**Steroids**

Systemic CSs are still the first-line treatment for PV. One of the main concerns in uncomplicated patients is when rapid control of the disease is achieved by monotherapy with CSs. Control of disease activity is usually achieved within several weeks. Complete remission on minimal treatment needs months, while complete remission off treatment often requires several months or even years of therapy.\textsuperscript{10}

A second debate often concerns whether to start with a low or high dose of CSs. The guidelines by EDF and European Academy of Dermatology and Venereology recommend initial prednisolone dose at 0.5 mg–1.5 mg/kg/d and if control of the disease is not reached within 2 weeks, a higher prednisolone dose (up to 2 mg/kg) could be administered.\textsuperscript{3} The optimal dose has not been validated. A controlled trial showed no significant difference regarding the duration of remissions and
relapse rates at 5 years in patients randomized to treatment with either low-dose oral prednisolone (1 mg/kg/d) or high-dose oral prednisolone (2.0–2.5 mg/kg/d).11 Once remission is induced and maintained with healing of the majority of lesions, the dose can be tapered by 25%. Reduction may be performed biweekly with slower decreases when doses below 20 mg/d are reached.12

CSs can be combined with an immunosuppressive agent, particularly when complications due to expected prolonged use (>4 months) such as hypertension, diabetes mellitus, and osteoporosis are expected.3 Even though the superiority of steroids plus adjuvant therapy over prednisolone monotherapy is debatable, considerable research effort has been directed at finding the optimal steroid-sparing agent.13,14 A recent systematic review that evaluated RCTs with adjuvant therapy with azathioprine, mycophenolate mofetil (MMF), cyclophosphamide, cyclosporine, intravenous immunoglobulin (IVIG), plasma exchange, and infliximab in PV patients concluded that adjuvants were not beneficial for achieving remission, but were found to collectively decrease the risk of relapse by 29%.15

If doses of prednisolone above 100 mg/d are required, pulse treatment with either oral or intravenous (IV) steroids may be considered. A regimen of IV betamethasone in combination with oral prednisolone in PV patients showed a shorter time to remission, clinical resolution (including oral lesions), and minor adverse effects when compared to monotherapy with oral prednisolone.16 A common pulse regimen used is 100 mg/d of IV dexamethasone for 3 days every 2–3 weeks.17 However, pulsed CSs do not appear to have additional benefit on top of conventional first-line treatment with oral prednisolone and immunosuppressive adjuvants.18 Most of the studies investigating the efficacy of pulse steroid treatment involve patients with refractory PV. In such patients, pulsed therapy with IV dexamethasone could be a reliable alternative when other options have failed.

Second-line treatment in the case of contraindications to glucocorticoids or complications due to expected prolonged use (>4 months) consists in the combined or single use of immunosuppressants such as azathioprine, MMF, dapsone, methotrexate, cyclophosphamide, and cyclosporine. In recent years, the use of IVIG and biologics such as infliximab, and especially rituximab, has been reported to produce excellent results in refractory cases.

Azathioprine
Azathioprine is one of the main adjuvants used in PV.19 It is considered a first-line adjuvant immunosuppressant according to the EDF guidelines. Dose varies between 1 and 3 mg/kg/d, based on the activity of the thiopurine methyltransferase (TPMT) enzyme, involved in the metabolism of the drug. When TPMT levels are high, normal doses of azathioprine (up to 2.5 mg/kg/d) are administered, while adults with PV and intermediate or low TPMT levels should receive a maintenance dose (up to 0.5–1.5 mg/kg/d). Azathioprine should not be used in patients with no TPMT activity. A dose of 50 mg/d could initially be administered, and if no idiosyncratic reactions occur, it could be increased after a week. In case of idiosyncratic reactions, it should be discontinued.20–22

The primary benefit of adjuvant azathioprine is its steroid-sparing effect.23 Azathioprine has been reported to require a lower cumulative CS dose for remission, with some investigators reporting superior steroid-sparing effect when compared to MMF and cyclophosphamide,24 while others concluded that cyclophosphamide is superior.13 Adverse events of adjuvant azathioprine treatment are decreased when compared to steroid monotherapy without any compromise in rates of clinical remission.25

Mycophenolate mofetil
MMF is a safe steroid-sparing agent.26 It is considered a first-line adjuvant immunosuppressant according to the EDF guidelines. The optimal dose is weight dependent with a dose of 2 g/d recommended for the average patient of 75 kg. Progressive dose increase by 500 mg/wk until the final dose of 2 g/d has been proposed to avoid gastrointestinal adverse events.1 Efficacy is debated. In a recent RCT, MMF (2 or 3 g/d) plus oral CSs was not found to be superior when compared with oral CSs and placebo in patients with mild or moderate PV. The primary end point was patients responding to treatment.27 Other investigators have also reported no clinical benefit using adjuvant MMF to steroids in patients with PV.28 MMF in combination with prednisolone seems to have a more prominent beneficial role in patients with relapses of PV29 or in cases of refractory PV who have failed previous treatments.30

Cyclophosphamide
Cyclophosphamide is considered a second-line immunosuppressant adjuvant therapy according to the EDF guidelines. It can be administered either as a 500 mg IV infusion or as 2 mg/kg/d orally.3 Cyclophosphamide monotherapy has not been able to demonstrate any benefit over prednisolone.31 Some authors report superiority over azathioprine or mycophenolate as adjuvant therapy.13 The potential long-term side effects (infertility, increased risk of cancer, infections,
agonist to be slowly tapered to a dose of 10–20 mg/wk.7 Literature data assessing its efficacy in PV treatment are scarce. A recent retrospective study reported that 21 out of 25 patients downgraded PV severity and were able to taper steroids after 6 months when using adjuvant therapy with 15 mg of methotrexate per week.34

**Methotrexate**

Methotrexate is a folic acid analog, a cytosine antimetabolite, and a broad spectrum antifolate. In PV, it is used as a steroid-sparing agent and is associated with various adverse effects such as myelosuppression, oral ulcerations, nausea, and stomatitis. Interestingly, it is not used in patients with short報 linea nigra. The recommended dosage is 15 mg/m² weekly. Additional beneficial effects can be observed in patients with suboptimal response to conventional therapies. Treatment can be performed over several days to avoid adverse effects due to the rapid distribution of the drug in the body. Methotrexate is used with caution in patients with renal impairment or those using immunosuppressive agents such as cyclophosphamide. Methotrexate is generally used in combination with glucocorticoids, azathioprine, or cyclophosphamide. In PV treatment, it is recommended to start with a low dose (5 mg/m²) and gradually increase to 15 mg/m² weekly, considering the patient’s response and tolerability. Methotrexate has been found to be effective in reducing disease activity, inflammation, and improving quality of life in patients with PV. However, the use of methotrexate is limited by the risk of adverse effects and the need for regular monitoring of liver and renal function.

**Infliximab**

Infliximab is a chimeric monoclonal antibody against tumor necrosis factor alpha (TNF-α). TNF-α has been found to be strongly expressed by the acantholytic cells in PV.39 There are several case reports and case series of PV patients successfully treated with infliximab.40-42 On the other hand, there are also several case series and a small comparative study showing no benefit in patients with PV treated with infliximab.43-45 There is also one case of a patient treated with infliximab for rheumatoid arthritis who developed pemphigus foliaceus.44 In the context of current evidence, infliximab does not have a role in the treatment of PV.

**Other therapeutic strategies**

In addition to the aforementioned agents, other therapeutic strategies for PV used by dermatologists worldwide in clinical practice include immunoabsorption, therapeutic plasma exchange – plasmapheresis – and extracorporeal photochemotherapy.

**Immunoadsorption**

Rapid removal of circulating autoantibodies against Dsg1 and Dsg3 can be achieved by immunoadsorption. It is indicated in patients with refractory PV when CSs combined with azathioprine or mycophenolate fail to control the disease. Four treatments of immunoadsorption on 4 consecutive days (2.5-fold plasma volume/d), repeated after 4 weeks, if needed, are the recommended schedule.3 Treatment could be undertaken in combination with immunosuppressive agents such as rituximab and cyclophosphamide.55,56 Contraindications include severe systemic infections, cardiovascular diseases,
and hemorrhagic diathesis. While immunoadsorption is far superior to plasmapheresis in terms of efficacy and safety, the high cost of the adsorbers is the major limiting factor.

Therapeutic plasma exchange – plasmapheresis
Plasmapheresis is an extracorporeal blood purification technique, in which the blood is continuously removed from the patient and separated into cellular components and plasma; the cellular compartments are returned to the patients along with replacement fluidlike albumin. Plasma exchange has been described as an effective adjuvant therapy in severe PV patients in controlling disease activity by reducing serum levels of autoantibodies. Plasma exchange can be performed using a centrifugation device used in blood banks. The double filtration plasmapheresis is a newer procedure that currently prevails because of its safety advantage. In double filtration plasmapheresis, immunoglobulins are selectively removed, while the loss of albumin is minimized. There is no standardized protocol for the number and frequency of sessions; however, four or five plasma exchanges, each exchange consisting of 1–1.5 plasma volumes, over a period of 7–10 days constitute an adequate short-term therapy to remove 90% of the total initial body immunoglobulin burden.

Plasma exchange is relatively safe, and the risk of infection associated with it is mainly due to the steroids and immunosuppressives given along with it. Other transient and minor adverse effects of plasma exchange have been reported include thrombocytopenia, hypogammaglobulinemia, fluid overload leading to hypertension and pulmonary edema, hypoproteinemia, anemia, leucopenia, and hypocalcemia. Because of the rapid fluid shift occurring as a result of removal of proteins, which maintain the osmotic pressure, it can lead to severe problems in patients with compromised cardiac function.

Extracorporeal photochemotherapy
Extracorporeal photochemotherapy involves the collection of mononuclear cells with a cell separator, their irradiation with ultraviolet-A (UV-A) light in the presence of 8-methoxypsoralen, and reinfusion of the treated cells into the patient. The mechanism of action has not been fully illuminated. Current knowledge suggests that extracorporeal photochemotherapy is an amplifier of the immunogenicity of class I-associated peptides that are present on the surface of the collected mononuclear cells. It has been approved by the US FDA (Food and Drug Administration) for the treatment of cutaneous T-cell lymphoma, and encouraging results have been reported in the management of nonmalignant disorders of the immune system such as PV, scleroderma, systemic lupus erythematosus, rheumatoid arthritis, autoimmune diabetes mellitus, rejection of cardiac and renal allograft, and chronic graft versus host disease. There are a few case series of patients with PV treated of extracorporeal photochemotherapy, with most of the patients exhibiting significant clinical improvement and no adverse effects.

Step-by-step therapy after control of the disease
The EDF proposed a useful treatment algorithm for use after the consolidation phase. The patients usually require 1–3 months for complete healing of the lesions.

• Start tapering steroids as soon as disease control is reached.
• Taper prednisolone by 25% every 2 weeks. When the patient reaches a dose <20 mg, taper more slowly. A 5 mg reduction every 4 weeks could be suitable for most of the patients.
• If less than 3 lesions reappear during tapering of oral CS therapy, raise dose to the last effective dose for the patient.
• If the patient presents with a relapse (>3 lesions), reincrease oral CS therapy, going two steps back in the previous dose until control of the lesions is achieved. Subsequently, restart tapering of systemic steroids. If you cannot obtain disease control, go back to the initial dose.
• If oral CSs are given as monotherapy, add an immunosuppressant.
• If oral CSs are already combined with an immunosuppressant, consider replacing a first-line immunosuppressant by another or the use of a second-line immunosuppressant including immunoadsorption, IVIG, or rituximab.
• Monitor the patient for adverse events, and remember that prolonged immunosuppressive therapy increases the risk of side effects.
• If you can monitor titers of anti-Dsg antibodies, remember that persistence of high levels of anti-Dsg1 has a positive predictive value for skin relapses, while the persistence of anti-Dsg3 IgG does not necessarily indicate a mucosal relapse.

Conclusion
CSs remain the gold standard treatment for PV. Finding the most effective steroid-sparing agent has formed much of the focus of recent research; however, evidence is inconclusive.
Azathioprine and MMF are the first line of steroid-sparing treatment. Rituximab is extremely effective in recalcitrant PV where other treatments fail to control the disease. Systemic treatment for PV is effective and has managed to lower the incidence of adverse events and morbidity compared to the past. However, as more studies incorporate the common definitions and guidelines, the level of evidence and strength of therapy recommendation will improve, resulting in shorter treatment and better quality of life for the patients.
