Abstract: Sepiapterin reductase participates in the biosynthesis of tetrahydrobiopterin, which plays very important roles in the pathogenesis of schizophrenia via dysregulation of neurotransmitter systems. Here, two single nucleotide polymorphisms (rs1876487 and rs2421095) in the promoter region of *SPR* were genotyped in 941 schizophrenic patients and 944 controls in a Han Chinese population using the SNaPshot technique. No significant differences were found in the distribution of alleles or genotypes of the two single nucleotide polymorphisms (SNPs) between schizophrenic patients and controls (all $P > 0.05$). Likewise, no haplotype was found to be associated with schizophrenia. However, sex-stratified analysis revealed that the frequencies of the A allele of rs1876487 and the A–A (rs2421095–rs1876487) haplotype were all significantly different between schizophrenia and controls in females ($P = 0.040$ and $P = 0.033$, respectively), but not in males. Additionally, luciferase reporter gene assays revealed that the A–A haplotype had significantly higher *SPR* transcriptional activity compared with the A–C haplotype in SH-SY5Y cells. Our data indicate that the two SNPs do not influence the risk of schizophrenia when using the total sample, but the A allele of rs1876487 and the A–A haplotype may contribute to protective roles for schizophrenia in females.

Keywords: schizophrenia, sepiapterin reductase, polymorphisms, Han Chinese population, transcriptional activity

Introduction

Schizophrenia is a complex mental disorder associated with a lifetime risk of approximately 1%, characterized by various abnormalities in thought, emotion, and behavior.¹ In recent years, several mechanisms for the pathophysiology of schizophrenia have been hypothesized, including altered homeostasis of different neurotransmitters, such as dopamine (DA), serotonin (5-HT), and glutamate (Glu), in different cortical and limbic and extrapyramidal pathways.^{2–4} In this regard, abnormalities in enzymatic activities involved in the biosynthesis or release of neurotransmitters may influence the functioning of neurotransmitters in the central nervous system and lead to psychiatric disorders including schizophrenia.^{5,6}

Tetrahydrobiopterin (BH₄), as a critical cofactor, is essentially required for the enzymatic activities of phenylalanine hydroxylase, tyrosine hydroxylase, and tryptophan hydroxylase; the last two enzymes participate in the rate-limiting steps of the biosynthesis of the monoamine neurotransmitter DA and 5-HT, respectively.⁷ Additionally, the increased release of DA, 5-HT, and Glu stimulated by an enhancement of intracellular BH₄ has been reported repeatedly, suggesting that BH₄ is a regulator of neurotransmitter release.^{8,9} In recent years, a significant plasma deficit

of total biopterin (a measure of BH₄) was reported in a large group of schizophrenic patients compared to healthy controls.^{10,11} Convergent animal and human evidence suggested that abnormalities in the biochemical cascades regulated by BH₄ possibly altered the neurotransmission of DA, 5-HT, and Glu, consequently contributing to the etiology of schizophrenia.

Sepiapterin reductase (SPR) participates in the final step of the pathway for de novo BH₄ biosynthesis.⁷ In a mouse model, *SPR* deficiency (*SPR*^{-/-}) led to a shortage of BH₄ in the brain, which was reduced to 40.5% compared to wild-type littermates.¹² Additionally, *SPR*^{-/-} mice exhibited disrupted homeostasis of DA and 5-HT that was accompanied by increased (three to four times) and sustained locomotor activity.¹³ Furthermore, human patients with *SPR* deficiency had low BH₄ levels in the cerebrospinal fluid.¹⁴ Based on the above evidence, we speculate that alterations in functional activity or the *SPR* expression level may represent the missing link that connects the reported abnormalities in BH₄ with the pathophysiology of schizophrenia.

SPR, the gene coding for SPR, is located on chromosome 2p13 and is composed of three exons within a 4.7 kb region.¹⁵ Karamohamed et al¹⁶ identified two single nucleotide polymorphisms (SNPs) (rs1876487 and rs2421095) in the promoter region of *SPR*, which may exert functional effects on the basal transcriptional activity and involve the regulation of *SPR* expression. In an in vitro study, McHugh et al¹⁷ showed that the A–A and G–A haplotypes (rs2421095–rs1876487) all significantly displayed lower expression levels in the basal *SPR* transcription rate than the A–C haplotype in both COS-7 and RN46A cells. Additionally, McHugh et al verified that individuals with haplotype pairs that consisted of the A–A and G–A haplotypes would increase the risk of bipolar disorder.¹⁷ Therefore, we hypothesized that polymorphism(s) in the *SPR* gene promoter may be responsible for the reduction in enzyme activity and the predisposition to psychiatric diseases, thus constituting a genetic risk factor for schizophrenia.

To our knowledge, a recent genome-wide association studies data analysis revealed that the two SNPs (rs1876487 and rs2421095) in the *SPR* promoter are not associated with schizophrenia susceptibility in the European population.¹⁸ However, an associated study between the two SNPs in the *SPR* gene and schizophrenia in the Han Chinese population has yet to be reported. Hence, we performed a study to explore the relationship between the two aforementioned SNPs of the *SPR* gene and schizophrenia in a case-control sample of Chinese subjects. Additionally, given the accumulating evidence suggesting that haplotypes have more

power to detect associations with the risk of complex diseases compared to single polymorphisms, we undertook an in vitro study to compare the transcriptional activities of *SPR* with different haplotypes in SH-SY5Y cells.

Materials and methods

Subjects

In this study, 941 unrelated schizophrenic patients (607 males and 334 females; mean age 35.50±13.81 years) and 944 healthy controls (598 males and 346 females; mean age 35.62±12.96 years) were recruited from the Department of Psychology and the Health Examination Center of the First Affiliated Hospital of Guangdong Medical College, respectively. The healthy controls were well matched to the schizophrenic patients based on sex and age ($P=0.601$ and 0.848 , respectively). All subjects were Han Chinese in origin. The patients were diagnosed by at least two psychiatrists according to the *Diagnostic and Statistical Manual of Mental Disorders IV* criteria for schizophrenia on the basis of structured clinical interviews and reviews of their hospital medical records. At the same time, the clinical symptomatology of the patients was assessed using the Positive and Negative Syndrome Scale. None of the subjects had histories of mental retardation, organic brain damage, drug or alcohol abuse, neurological disorders, autoimmune disorders, and metabolic illnesses. All healthy controls were interviewed by a psychiatrist and screened using unstructured clinical interviews. Additionally, they lacked family histories (first-degree relatives) of psychiatric illness, serious somatic illness, and substance abuse diagnosis (excluding nicotine dependence). The study protocol was approved by the Ethics Committee of Guangdong Medical University and written informed consent was obtained from all participants. Finally, the patients' capacity to consent was confirmed by the family member when required.

Genotyping

Genomic DNA was extracted from ethylene diamine tetraacetic acid-treated peripheral blood using the TIANamp Blood DNA Kit (Tiangen Biotech, Beijing, People's Republic of China). In total, 1,885 individuals were genotyped for two SNPs (rs1876487 and rs2421095) located in the *SPR* gene using the SNaPshot technique (Thermo Fisher Scientific, Waltham, MA, USA) as described previously.¹⁹ The polymerase chain reaction primers used for rs1876487 were 5'-AGGGCTGGAAGTGGGAGGAAAT-3' (forward primer) and 5'-TGGTTCCTTGGGATCTGGTTC-3' (reverse primer), and the primers used for rs2421095 were 5'-CCTCCAAGTTGTTTCTTCTTAGAGTTG-3' and 5'-TTAGCCARTTCCCCACAGG-3'.

Cloning and dual luciferase assays

Initially, an approximately 1,230 bp region including a 5'-UTR genomic region of *SPR* (−1204 to +26 bp) from an individual A homozygous for rs241095 and rs1876487 was amplified by polymerase chain reaction using Expand High Fidelity DNA polymerase (Roche) and a pair of primers 5'-CGGGGTACCCAGTTTGGGCCACAGAGCGAGACT C-3' and 5'-GGAAGATCTTGGCACCCGAGACCAGGCA GGAGGC-3'. The resulting haplotype served as the reference haplotype A–A. The genomic fragments amplified with the Kpn1 and BglII sites were cloned into a pGL4 Basic Vector (Promega Corporation, Fitchburg, WI, USA). The C polymorphism of rs1876487 was then sequentially altered using a QuikChange II site-directed mutagenesis kit (Stratagene, Santa Clara, CA, USA) according to the manufacturer's instructions. All of the constructs were confirmed by sequence analysis. The reporter constructs were introduced by Effectene-mediated transfection (Qiagen NV, Venlo, the Netherlands) into the SH-SY5Y neuroblastoma cell lines. Luciferase activity was measured according to our previous description.²⁰ Each assay was conducted in triplicate in two independent experiments.

For the functional prediction of the candidate SNP, we used Transcription Element Search System software (<http://www.cbil.upenn.edu/cgi-bin/tess/tess>) to analyze potential protein binding sequences containing SNP rs1876487. In order to identify possible changes to transcription factor binding site (TFBS) due to the presence of the rs1876487 polymorphism, we performed the TFBS in two different situations: a TFBS search when the sequence possessed the

ancestral allele (C) and a TFBS search in a sequence in which the polymorphism (A) was present.

Statistical analyses

The demographic and clinical data between the schizophrenic patients and the controls were compared using Student's *t*-tests or Pearson's chi-squared tests as appropriate. Hardy–Weinberg equilibrium and statistical analyses to compare allelic and genotypic distributions were performed using Pearson's chi-squared tests and Fisher's exact two-tailed tests when appropriate. All analyses were performed using SPSS 17.0 software for Windows. The criterion for significance was set at $P < 0.05$ for all of the tests and *P*-values were two-sided.

Additionally, the linkage disequilibrium status of the two SNPs was determined using the Haploview 4.2 program. Only those haplotypes with frequencies greater than 1% were examined. For the luciferase reporter gene assay data analysis, statistical comparisons between two groups were assessed using Student's *t*-test.

Results

Association study of SNPs (rs1876487 and rs2421095) and schizophrenia

The distribution of genotypes and alleles of the two SNPs (rs1876487 and rs2421095) reached the Hardy–Weinberg equilibrium in both schizophrenic patients ($P=0.47$ and 0.91 , respectively) and controls ($P=0.88$ and 0.91 , respectively). Allele and genotype frequencies for the *SPR* gene are shown in Table 1. In terms of the rs1876487 polymorphism, the

respective frequencies of CC, CA, and AA genotypes were 91.0%, 8.9%, and 0.1% in the schizophrenic patients, and 89.5%, 10.2%, and 0.3% in the control group, respectively. Due to the low frequency of the AA genotype, the AA genotypes were grouped with the CA genotypes and were referenced as A allele carriers. For rs2421095, none of the individuals had the GG genotype in our study population, and the frequencies for the AA and AG genotypes in the schizophrenic patients and the controls were almost identical (99.3% and 0.7%, respectively). There were no significant differences in the distribution of the two aforementioned SNPs between our schizophrenic patients and controls (all $P > 0.05$). Additionally, in the sex-stratified analysis, the genotype and allele distributions of rs1876487 were significantly different between schizophrenia and controls in females ($P = 0.045$ and 0.040 , respectively), but not in males (Table 2).

For further analysis, our study also focused on the description of relevant clinical characteristics of 543 schizophrenic patients distributed by genotype. None of the CC genotype and A allele carriers of rs1876487 showed significant associations with clinical characteristics, such as age at onset, duration of illness, Positive and Negative Syndrome Scale score, family psychotic history, and other factors (Table 3).

Linkage disequilibrium analysis and haplotype analysis

We also performed a haplotype analysis based on the two SNPs rs2421095 and rs1876487, and a weak linkage disequilibrium was observed ($D' = 0.607$, $r^2 = 0.026$). Two out of four possible haplotypes revealed at least 1% frequencies in either the schizophrenic patients or the controls. Analysis of the haplotype frequencies demonstrated no significant difference between the schizophrenic patients and controls. Furthermore, in the female subgroup, the A–A (rs2421095–rs1876487) haplotype was significantly different between the schizophrenic patients and the controls ($P = 0.033$, odds ratio [OR] = 0.575, 95% confidence interval [CI] = 0.344–0.961) (Table 4).

Functional analysis of different *SPR* promoter haplotypes

As shown in Figure 1, the promoter activity driven by the A–A haplotype was 1.2-fold higher than the A–C haplotype, and the difference was significant ($P < 0.05$). Our data suggested that the A allele of rs1876487 might improve the *SPR* promoter activity.

To clarify the underlying molecular mechanism of the influence of SNPs on *SPR* promoter activity, the putative

TFBS were performed using Transcription Element Search System software. The analysis (data not shown) predicted that the C allele of rs1876487 would generate an SP1-binding site, but the A allele would not.

Discussion

Given the critical role of SPR in neurotransmitter production, we sought to test the hypothesis that SPR would be involved in the pathogenesis of schizophrenia. In this study, the genetic analysis of SPR polymorphisms between the schizophrenic patients and the controls indicated that there were no significant differences in terms of the distribution of the rs1876487 and rs2421095 genotypes and alleles. Additionally, we have demonstrated that the GG genotype (rs2421095) was not detected in either the patients or the controls in our study. Furthermore, the A allele frequency of rs1876487 and the G allele frequency of rs2421095 were lower in our Chinese population (5.4% and 0.4%)

than the corresponding frequencies in the USA (21.9% and 4.7%)²¹ and New Zealand (30.0% and 12.0%),¹⁷ but were similar to those in the Chinese Beijing population of the International HapMap Project (<http://hapmap.ncbi.nlm.nih.gov/>). The results suggest that there is an ethnicity-related variation in the distribution of the two aforementioned SNPs in the SPR gene. Our findings suggest that the two polymorphisms may not contribute to schizophrenia susceptibility in the Han Chinese population. However, we did not clarify the relationship between other SNPs in the SPR gene and schizophrenia. Based on these, the identification of other polymorphisms in the SPR gene associated with schizophrenia and replication in other ethnic populations requires further study.

Interestingly, the stratified analysis by sex revealed that the genotype and allele frequencies of rs1876487 between schizophrenic patients and controls in females showed significant differences ($P=0.045$ and 0.040 , respectively), but

not in males. These results are likely to suggest a sex specific association for rs1876487 of the *SPR* gene with schizophrenia. Our finding is not surprising because many studies have reported that there were sex differences in the pathogenesis of schizophrenia. Grigoriadis and Seeman²² suggested that estrogen exerts a protective effect against schizophrenia. Additionally, estrogen regulates the dopaminergic and serotonergic activities in different brain regions of patients with schizophrenia.²³ In this study, the frequency of the A allele of rs1876487 in the schizophrenic patients was lower compared to the controls in the female subgroup (3.9% vs 6.4%, OR = 0.596, 95% CI = 0.363–0.980), suggesting that the A allele of rs1876487 may have a protective role in female schizophrenia. Additionally, we predicted that the C allele of rs1876487 generated a SP1-binding site, but the A allele would not. It has been reported that SP1 could activate the expression of some genes and downregulate that of other genes.²⁴ Additionally, SP1 is involved in the regulation of several genes related to schizophrenia, such as DA receptors and mitochondrial complex I genes.²⁵ However, the potential relationship between SP1 and *SPR* expression is not yet understood. Furthermore, a study by Sumi and Ignarro verified that estrogen-related receptor α increases the SP1 expression in COS-7 cells.²⁶ Taken together, it can be speculated that estrogen stimulates SP1 expression through estrogen-related receptor α , and then regulates *SPR* gene transcription in females. However, further investigation is required to clarify the interaction between estrogen and the *SPR* gene in the central nervous system. Analysis of haplotype-based association in our genetic study revealed that no significant differences existed in the distribution of the

A–C and A–A haplotypes between the schizophrenic patients and the controls. Intriguingly, in our female subjects, the frequency of the A–A haplotype was higher in the controls (6.1% vs 3.6%), indicating that this haplotype may constitute a protective factor for schizophrenia ($P = 0.033$, OR = 0.575, 95% CI = 0.344–0.961). This result is consistent with our functional analysis that the A–A haplotype significantly induced higher *SPR* transcriptional activity compared with A–C haplotype in SH-SY5Y cells, which would lead to increased *SPR* expression and upstream effects on BH_4 -mediated neurotransmitter production. However, in a previous study, McHugh et al¹⁷ reported that the A–A haplotype displayed significantly lower expression levels in the basal transcription rate of the *SPR* gene than the A–C haplotype in both COS-7 and RN46A cells. Several reasons may partially account for such conflicting results. First, different cell types or tissues may have diverse transfection activities. Second, the two SNPs in different ethnic populations share different D' and r^2 values, and may thus have different levels of linkage disequilibrium with other functional SNPs, which alter the promoter activity of the *SPR* gene. However, more studies are still needed to elucidate the function of the two-SNP *SPR* promoter haplotypes in various cell lines.

Conclusion

The results from our study might provide evidence that the two SNPs (rs1876487 and rs2421095) in the *SPR* promoter are not associated with schizophrenia susceptibility in the Han Chinese population. However, the A allele of rs1876487 and the A–A haplotype may contribute to protective roles in female schizophrenia. Thus, to confirm our finding, replication in a large sample size, especially for females and other ethnic populations, is required. Furthermore, the identification of other polymorphisms in the *SPR* gene associated with schizophrenia would warrant further investigation.

Neuropsychiatric Disease and Treatment

Publish your work in this journal

Neuropsychiatric Disease and Treatment is an international, peer-reviewed journal of clinical therapeutics and pharmacology focusing on concise rapid reporting of clinical or pre-clinical studies on a range of neuropsychiatric and neurological disorders. This journal is indexed on PubMed Central, the 'PsycINFO' database and CAS,

Submit your manuscript here: <http://www.dovepress.com/neuropsychiatric-disease-and-treatment-journal>

and is the official journal of The International Neuropsychiatric Association (INA). The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
