Background: Chronic kidney disease (CKD) has been defined as a coronary artery disease risk equivalent. Therefore, the current guideline has been recommended for CKD patients to reach and maintain a low-density lipoprotein-cholesterol (LDL-C) goal of less than 100 mg/dL. However, the data regarding the achievement of LDL-C goal in these patients is lacking.

Objective: This study was conducted to evaluate the types of dyslipidemia affecting patients with CKD stages 3 and 4 and to determine whether these patients achieved LDL-C goal.

Methods: We performed a retrospective chart review of patients with CKD stage 3 or 4 and dyslipidemia who were followed-up at Siriraj Hospital between October 2011 and September 2012.

Results: In total, 150 patients with CKD stage 3 or 4 and dyslipidemia were recruited. The mean age was 72 ± 10 years, and the body mass index was 25.6 ± 4 kg/m²; 60% had CKD stage 3 with an estimated glomerular filtration rate of 34 ± 12 mL/min/1.73 m², and 54% had type 2 diabetes. The percentage of patients with hypercholesterolemia was 78%, hypertriglyceridemia 54%, and low high-density lipoprotein-C 36%. Of these, 52% had mixed hyperlipidemia. Statin treatment was prescribed to 87% of the patients, of which only 31.3% achieved the LDL-C goal according to the National Cholesterol Education Program and the European Society of Cardiology/European Atherosclerosis Society recommendations. Patients who did not achieve the LDL-C goal had a higher cholesterol level at diagnosis and higher prevalence of type 2 diabetes and stroke than those who achieved it.

Conclusion: Two-thirds of CKD patients with hyperlipidemia had mixed hyperlipidemia. Despite the high frequency of statin treatment, only one-third of patients with CKD achieved the LDL-C goal. Thus, a developmental plan for the management of dyslipidemia in patients with CKD should be implemented to increase their achievement of the LDL-C goal.

Keywords: chronic kidney disease, hyperlipidemia, LDL-C, dyslipidemia

Introduction

Chronic kidney disease (CKD) is a common health issue, and its incidence may continue to increase worldwide given the rise in type 2 diabetes and other CKD risk factors.¹ Data from the Thai Screening and Early Evaluation of Kidney Disease study² demonstrated that CKD prevalence in the Thai population increased compared with the incidence reported in a previous study (17.5% vs 4.6%–13.8%, respectively). Among Thai patients with CKD, 27.5% had hypertension and 11.9% had type 2 diabetes, which were the two main causes of CKD.² A previous study³ has shown the association between the reductions of estimated glomerular filtration rate (eGFR) and the increase of cardiovascular events and accelerated atherosclerosis, which result in increased morbidity and mortality. Prevention and treatment of cardiovascular disease are major

considerations in the management of individuals with CKD.⁴ Another recent study⁵ showed that lowering cholesterol can decrease cardiovascular morbidity and mortality in CKD patients. Therefore, the National Cholesterol Education Program (NCEP)⁶ and the European Society of Cardiology/the European Atherosclerosis Society⁷ have defined CKD as a coronary artery disease risk equivalent and recommend a low-density lipoprotein-cholesterol (LDL-C) goal of 100 and 70 mg/dL for CKD patients, respectively. However, data regarding the type of dyslipidemia in CKD patients in Thailand is lacking, especially for patients with CKD stages 3 and 4 who have marked impairment of eGFR. Therefore, this study was conducted to evaluate the types of dyslipidemia that affect patients with CKD stages 3 and 4 and to determine whether the LDL-C goal was achieved in these patients.

Materials and methods

Study population

Patients who had CKD stage 3 or 4 and dyslipidemia, according to International Classification of Diseases 10 (N18.9) criteria, and were followed-up for at least 1 year in the internal medicine outpatient department (OPD) at Siriraj Hospital between October 1, 2011 and September 30, 2012, were recruited to allow sufficient time for the health care provider to adjust the lipid-lowering agent. In this study, eGFR was calculated using the National Kidney Foundation Chronic Kidney Disease Epidemiology Collaboration equation and eGFR calculator program. CKD stages 3 and 4 were defined as the estimated eGFR 30–59 mL/min/1.73 m² and 15–29 mL/min/1.73 m², respectively. Patients at other stages of CKD, those who had received the lipid-lowering agents before attending OPD at Siriraj Hospital and those who did not have lipid profiles at the time of diagnosis and at the last visit to the internal medicine OPD were excluded. The Siriraj Institutional Review Board approved the study, which was conducted in compliance with the Declaration of Helsinki. Based on the type of study, the Siriraj Institutional Review Board waived the need for formal informed consent.

Data collection and outcome measurements

The computer-based data of each patient were reviewed. Data were extracted as follows. We obtained the baseline and laboratory characteristics, including age, sex, body mass index, eGFR, CKD stage, comorbidities, type and dosage of cholesterol-lowering agent used, and lipid profile at the time of diagnosis and at the last visit to the internal medicine OPD.

The definition of dyslipidemia was categorized as follows: hypercholesterolemia was defined as cholesterol level greater than 200 mg/dL and/or LDL-C level greater than 100 mg/dL; hypertriglyceridemia, as triglyceride level greater than 150 mg/dL; and low high-density lipoprotein-cholesterol (HDL-C) lower than 40 mg/dL in men and 50 mg/dL in women. Patients who had more than one abnormal lipid component were defined as having mixed hyperlipidemia. Statin potency was classified as low, moderate, and high according to the 2013 the American College of Cardiology/American Heart Association (ACC/AHA) Blood Cholesterol Guideline.⁸ In brief, the low-potency statin was simvastatin 10 mg. The moderate-potency statins included simvastatin 20–40 mg, atorvastatin 10–20 mg, and rosuvastatin 5–10 mg. The high-potency statins included simvastatin, atorvastatin, and rosuvastatin at doses higher than 40, 20, and 10 mg, respectively. Add-on ezetimibe to a moderate-potency statin was also considered as high potency.

The achievement of the LDL-C goal according to the NCEP Adult Treatment Panel III recommendation was evaluated using the lipid levels at the last visit to the internal medicine OPD. For patients with CKD and diabetes or atherosclerotic diseases, such as peripheral arterial disease, abdominal aortic aneurysm, symptomatic carotid artery stenosis, stroke, and coronary artery disease, the LDL-C goal was 70 mg/dL, whereas for patients with CKD without comorbidities, the LDL-C goal was 100 mg/dL. The “achieved LDL-C goal” group consisted of patients with an LDL-C level lower than the goal LDL-C and the “did not achieve LDL-C goal” group consisted of patients with an LDL-C greater than the goal LDL-C. Factors associated with achieving the LDL-C goal were then evaluated.

Statistical analysis

Statistical analysis was carried out with SPSS software, version 18 (SPSS Inc., Chicago, IL, USA). Continuous data were expressed as mean \pm standard deviation or median (min, max) as appropriate. Comparisons between groups were analyzed by the Student's *t*-test. Categorical data were expressed as percentages. Comparisons were analyzed by the chi-square test or Fisher's exact test. Statistical significance was declared if the *P*-value was less than 0.05.

Results

Baseline characteristics

In total, 150 patients diagnosed with CKD stage 3 or 4 and dyslipidemia were included in this study. The characteristics of the subjects are described in Table 1. The patients

Table 1 Clinical and laboratory characteristics

Characteristics	N=150
Age (years)	72±10
Male	96 (64.0)

(Table 2). The mean lipid levels at the time of diagnosis and at the last visit to the OPD are shown in Table 2. Most of the subjects were treated with low- and moderate-potency statins (37% and 43%, respectively).

Achievement of LDL-C goal

Only 47 patients (31.3%) achieved the LDL-C goal according to the NCEP recommendation. As shown in Table 3, a greater proportion of patients in the “did not achieve LDL-C” group had comorbidities, including type 2 diabetes and stroke, compared with the patients in the “achieved LDL-C” group; therefore, in this group, the LDL-C goal for the former should

be lower than that for the “achieved LDL-C” group. These patients also had a higher cholesterol level at the time of diagnosis than those in the “achieved LDL-C” group. Although the “did not achieve LDL-C” group had higher cholesterol levels at baseline and the LDL-C goal should have been lower, it would be expected that the “did not achieve LDL-C” group would have required treatment with statins of higher potency. However, the potency of statins used in these two groups was not significantly different as shown in Figure 1.

Discussion

In the present study, approximately half of the patients with CKD stage 3 or 4 and dyslipidemia had mixed hyperlipidemia. These findings are consistent with the results of a previous study⁷ in which most patients with CKD stage 3–5 had mixed dyslipidemia. These data have important clinical implications because patients with mixed dyslipidemia require combination treatment with statins and fibrates for the management of their abnormal lipid level. These two types of drugs have significant drug interactions,⁹ and thus, clinicians who manage these patients should be cautious when prescribing such medications.

According to our results, 87% of the patients received statin treatment. Despite the high frequency of statin treatment, only 31.3% of the patients achieved the LDL-C goal. According to our results, patients whose LDL-C goal should have been lower, and who required treatment with statins of higher potency, received statins of low-to-moderate potency. We hypothesized that the following were possible reasons why these patients did not achieve the LDL-C goals: limited knowledge of clinicians, fear of statin-related side effects led to poor treatment adherence, and the goal of LDL-C in patients with comorbidities was markedly low, especially for patients with type 2 diabetes.

Despite the fact that CKD has been known to be a coronary artery disease risk equivalent since 2004,¹⁰ no previous studies

had demonstrated that lowering cholesterol could reduce cardiovascular morbidity and mortality among these patients until recently.¹¹ It was recently demonstrated that reduction of LDL-C with simvastatin plus ezetimibe could safely reduce the incidence of major atherosclerotic events in a wide range of patients with advanced CKD. Moreover, recent meta-analysis demonstrated that CKD patients could benefit from statin treatment in terms of cardiovascular events, mortality, and renal outcomes.¹² General practitioners may not be aware of the benefit of lowering LDL-C in these patients. Thus, a developmental program should be launched to include updated clinical policies and treatment guidelines for patients with dyslipidemia with various comorbidities, especially CKD.

Based on our study results, patients who did not achieve the LDL-C goal had a higher cholesterol level at baseline and had comorbidities for which a lower LDL-C goal should be established; therefore, these patients should have been treated with statins at a high dose or needed high-potency statins to achieve the LDL-C goal. The adverse effects of lipid-lowering drugs, including myositis and hepatitis, are commonly found in patients with advanced CKD, particularly those exposed to a high statin dose or potency. Therefore, it is likely that clinicians prescribed a low dose or a statin of low-to-moderate potency to prevent or ameliorate these adverse effects, which could explain the lack of achievement of the LDL-C goal in this group of patients.

The main limitation of this study was its retrospective design, which involved the review of computer-based patient data. Therefore, we did not have data on the duration of statin treatment. We did not know whether the health care provider adjusted the patient treatment regimens. However, we recruited only the patients who had been in follow-up at the OPD for at least 1 year. We considered that this was sufficient time for the health care provider to adjust the regimens. Although the Kidney Disease Improving Global Outcomes organization developed and released a clinical practice guideline that includes recommendations of statin doses for patients with CKD,¹³ further study should be performed to evaluate the dose and type of statin treatment for these patients.

Conclusion

Among CKD patients with hyperlipidemia, approximately two-thirds of the patients had mixed hyperlipidemia. Despite the high frequency of statin treatment, only one-third of CKD patients achieved the LDL-C goal. The high level of cholesterol at diagnosis and low LDL-C goal, such as that observed for patients with type 2 diabetes and stroke were probably the main factors leading to failure to achieve the

Figure 1 Comparison of the potency of statins used for patients who did not achieve the LDL-C goal (open bar) and those who achieved the LDL-C goal (solid bar).
Abbreviation: LDL-C, low-density lipoprotein-cholesterol.

LDL-C goal. Thus, a developmental plan for the management of dyslipidemia in CKD patients should be launched to increase the percentage of patients who achieve the LDL-C goal, which could result in decreased cardiovascular morbidity and mortality among these patients.
