Background: It has been found that nuclear factor erythroid 2-related factor 2/antioxidant response element (Nrf2–ARE) signaling pathway plays a role in antioxidative response, anti-inflammatory response, and neuron-protection in intracerebral hemorrhage (ICH). The aim of this study is to explore mechanisms underlying the perifocal neuroprotective effect of the Nrf2–ARE signaling pathway after ICH.

Methods: There were a total of 90 rats with basal ganglia hemorrhage, which were randomly divided into the following four groups: ICH (Sprague-Dawley rats with autologous femoral arterial blood injection into the basal ganglia), sulforaphane (SFN) (SFN was intraperitoneally administered into rats), retinoic acid (RA) (RA was intraperitoneally administered into rats), and dimethyl sulfoxide (the rats were treated with dimethyl sulfoxide). We observed the neurological score of the rats in the different groups, and collected brain tissues for immunofluorescence, Western blot, and reverse transcription polymerase chain reaction to detect expression of Nrf2, heme oxygenase (HO-1), nuclear factor-κB (NF-κB), and tumor necrosis factor-α (TNF-α).

Results: The results indicated that neurological dysfunction of rats was significantly improved in the SFN group, and the expressions of NF-κB and HO-1 in tissues surrounding the hemorrhage were increased. Also, the level of NF-κB and TNF-α were reduced compared to the ICH group. The RA group exhibited more severe neurological dysfunction and lower levels of NF-κB and HO-1 than the SFN and ICH groups. Compared to the ICH group, the NF-κB and TNF-α expression in the RA groups was increased. In conclusion, RA inhibits Nrf2 dissociation and translocation into nucleus, thereby suppressing the anti-inflammatory effect of Nrf2–ARE signaling pathway. The activation of Nrf2–ARE signaling pathway by SFN can elevate expression of antioxidant enzyme HO-1, reduce perifocal inflammatory response after ICH, and thus may play a neuroprotective role.

Conclusion: The results suggest that Nrf2–ARE signaling pathway may serve as a new target for treatment of perifocal inflammatory injury caused by ICH.

Keywords: cerebral hemorrhage, injuries, NF-E2-related factor 2, antioxidant response elements

Introduction

The incidence, morbidity, and mortality of intracerebral hemorrhage (ICH) remain high, yet the existing medical and surgical treatment methods are unable to prevent perifocal damage. The activation of inflammatory cells and the release of inflammatory cytokines in the perifocal tissues after ICH are key factors in triggering secondary brain damage.1,2 As an important regulator of the inflammatory response, nuclear transcription factor-κB (NF-κB) can trigger and amplify the inflammatory response, and inhibition of the NF-κB inflammatory response after ICH may alleviate neuronal damage. In addition, nuclear factor erythroid 2-related factor 2 (Nrf2) is an important...
regulator in the antioxidative response of the cells, it interacts
with antioxidant response element (ARE), and plays a wide
range of cytoprotective roles in antioxidative, antiapoptotic,
and anti-inflammatory responses and neuroprotection.

Studies by our group and others have found that the Nrf2
activator sulforaphane (SFN) can protect neurons by induc-
ing the expression of heme oxygenase (HO-1) and quinone
oxidoreductase 1 to protect neurons. HO-1 can serve as
an important antioxidant enzyme and antagonize oxidative
stress caused by brain damage. Therefore, the Nrf2 gene may
become a new target for treatment of perifocal damage after
ICH. In a previous study, Nrf2 knockout mice and normal
mice were compared to explore the relevant protein expres-
sions in the Nrf2–ARE signaling pathway and its role in
ICH, and the results suggested that compared to normal mice,
the Nrf2 knockout mice showed more severe neurological
deficits after ICH, and the protein expression downstream of
the pathway was very low. To investigate the mechanisms
of Nrf2–ARE pathway further, we used SFN to activate the
Nrf2–ARE signaling pathway, and retinoic acid (RA) was
used to inhibit the Nrf2–ARE signaling pathway to examine
the neuroprotective effect of HO-1 on perifocal tissues after
ICH and to explore the underlying mechanisms. The goal
was to control perifocal damage caused by ICH from its
underlying molecular mechanisms, and to save neurons to
the maximal possible degree.

Materials and methods

Experimental animals

In the present study, male Sprague Dawley rats (purchased
from Hunan Slack Jiangda Laboratory Animal Co., Ltd.
(Changsha, Hunan province, People’s Republic of China);
certificate number: SCXK [Xiang] 2009-0004) were used,
and their body weights ranged from 250 to 300 g. All animal
handling procedures were performed according to the Guide
for the Care and Use of Laboratory Animals of the National
Institutes of Health and followed the guidelines of the Animal
Welfare Act. All animal experiments were approved by the
Experimental Animal Ethical Committee of Affiliated Hospital
of Jiujiang University.

Main reagents and instrument

RA (specification: 1 g), SFN (specification: 5 mg), and dim-
ethyl sulfoxide (DMSO) (specification: 100 mL/bottle) were
purchased from Sigma-Aldrich Co. (St Louis, MO, USA).
The following primary antibodies were used: rabbit anti-rat
Nrf2 polyclonal antibody and goat anti-rat HO-1 polyclonal
antibody purchased from Abcam; and rabbit anti-rat NF-κB polyclonal antibody and rabbit anti-rat
tumor necrosis factor (TNF-α) polyclonal antibody purchased from Cell Signaling Technology (Beverly, MA, USA). The
following secondary antibodies were used: dog anti-rabbit
polyclonal antibody labeled with Cy3 fluorescein and dog
anti-goat polyclonal antibody labeled with fluorescein iso-
thiocyanate, which were purchased from Abcam; and rabbit
anti-rat β-actin polyclonal antibody, which was purchased
from Abcam. The sodium dodecyl sulfate-polyacrylamide
gel electrophoresis (SDS–PAGE) gel preparation kit was pur-
chased from Beyotime Institute of Biotechnology (Shanghai,
People’s Republic of China). Instruments included the follow-
ing: animal skull stereotaxic apparatus, electronic analytical
balance, image analyzer, and ultraviolet spectrophotometer.

Establishment of rat ICH model and
magnetic resonance imaging verification

The rats were subjected to fasting without water deprivation
8 hours before surgery. The method reported by Deinsberger
et al was used for slow blood injection on stereotax at
3 mm lateral to the right side of the anterior fontanelle and a
penetration depth of 5 mm. Forty microliter autologous blood
was slowly injected into the basal ganglia to establish a rat
ICH model. For each rat, blood injection took approximately
30 minutes. Garcia 18-point test was performed to assess
the neurological function of the rats, and those with a score
≥3 were considered usable subjects. In collaboration with
the Radiology Department of Tongji Hospital, affiliated with
Huazhong University of Science and Technology and Tongji
Medical College, the GE signa Excite HD 3.0 T MR scanner
was used to examine the hematoma 3 hours after the ICH had
been established (Figure 1). The scan sequence and details
were listed as follows: coronal section T2WI (weighted image),
T2*WI, thickness 0.8 mm, interval 0.1 mm. If a notable round,
oval, or irregularly-shaped hematoma was observed, the model
was considered to be successfully established. If there was
blood reflux into the needle tract, blood in the ventricles, or
death, the animal was excluded from the study.

Blood pressure monitor

The pentobarbital sodium was injected intraperitoneally, and
the blood pressure was monitored during the experiments. The
blood pressure was monitored by using tail venous manometry
during the experiments. The monitor indicated that the blood
pressure was stable during the whole of the experiments.

Drug dosage and route of administration

Five milligrams SFN was dissolved in 5 mL DMSO and
intraperitoneally administered postoperatively into the rats
at a concentration of 1 mg/kg twice daily.
One gram RA was dissolved in DMSO to a final concentration of 20 mg/mL and intraperitoneally administered 30 minutes after the surgery at a dose of 10 mg/kg.

**Experimental groups and sample collection**

One-hundred healthy male Sprague–Dawley rats, weighing 250–300 g, were used in the experiments. There were a total of 90 rats with basal ganglia hemorrhage, which were randomly divided into the following four groups: ICH, SFN, RA, and DMSO group. Each group was divided into the following five subgroups: 6 hours, 1 day, 2 days, 3 days, and 7 days group (after ICH), and each subgroup contained five rats.

The rats were anesthetized and subjected to a thoracotomy at the corresponding time points. The heart was rapidly exposed, and a perfusion tube was inserted from the left ventricle to the root of the aorta. A small cut was made on the right atrial appendage with scissors. Then, 200 mL 4°C saline was infused until the effluent fluid was clear, and 4% paraformaldehyde was used for perfusion until the limbs of the rat were rigid. The animal was then decapitated and its brain collected, placed in 4% paraformaldehyde for 24 hours, and subsequently subjected to frozen sectioning at a slice thickness of 5 μm for immunofluorescence staining.

**Neurological score**

The Garcia 18-point method was used to evaluate the neurological function of rats after ICH. The scores were obtained 24 hours before surgery, immediately before surgery, and 6 hours, 1 day, 2 days, 3 days, and 7 days after surgery.

**Immunofluorescence tests for detecting the expressions of Nrf2, HO-1, NF-κB, and TNF-α**

Nrf2-, HO-1-, NF-κB-, and TNF-α-positive cells were detected as follows: 1) frozen 5 μm thick sections of brain tissue were...
fixed in precooling paraformaldehyde for 20–30 minutes; 2) phosphate-buffered saline (PBS) rinse was performed for 5 minutes three times, followed by membrane rupture using 0.25% triton for 15 minutes; 3) PBS rinse was performed for 5 minutes, three times, followed by blocking using 10% Bull serum albumin (BSA) for 60 minutes; 4) PBS rinse was performed for 5 minutes, three times, followed by incubation with primary antibody at 4°C overnight (approximately 12 hours); 5) PBS rinse was performed for 10 minutes, three times, followed by incubation with second antibody at room temperature for 2 hours, and all the next steps were performed in darkness; 6) PBS rinse was performed for 10 minutes, three times, followed by 4',6-diamidino-2-phenylindole staining for 15 minutes; 7) PBS rinse was performed for 5 minutes, three times, followed by mounting with glycerol, and fluorescent microscope was used for observation and taking images; and 8) OPTPro imaging analysis system (LI-COR Biosciences, Lincoln, NE, USA) was used to scan and analyze the images. At 200× magnification, images from five nonoverlapping fields were analyzed for cell counts and the mean was calculated.

Western blot analysis for determining the protein expression levels of Nrf2, HO-1, NF-κB, and TNF-α

The brain tissues were removed from the −80°C freezer and slowly thawed at room temperature. Tissues within 4 mm of the hematoma were collected and a radioimmunoprecipitation assay lysis buffer containing a protease inhibitor cocktail (1:9, ie, 100 mg brain tissue added into 0.9 mL buffer) was added before the tissue was subjected to homogenization. All the above steps were performed on ice. After homogenization, the mixture was placed on ice for another 30 minutes to allow full cleavage of the proteins. Next, centrifugation at 12,000× g for 30 minutes at 4°C was performed and the supernatant was collected. The bicinchoninic acid (BCA) assay was performed to measure protein concentration (BCA kit purchased from Beyotime Institute of Biotechnology), and based on the protein concentration, the sample volume in each well was calculated so that the total protein concentration in all wells was equal. After the loading buffer had been added, the protein was boiled before it was subjected to electrophoresis on 10% SDS–PAGE gel. After completion of electrophoresis, wet transfer of the membrane onto a nitrocellulose membrane (0.45 μm) was performed at 100 V constant voltage for 90 minutes. Then, the membrane was blocked in 5% skim milk at room temperature for 1 hour. After blocking, anti-Nrf2 (1:1,000, ab31163; Abcam), anti-HO-1 (1:2,000, ab13243; Abcam), anti-NF-κB (1:1,000, CST#8242; Cell Signaling Technology), and anti-β-actin (1:1,000, 70-Mab1445; Sigma-Aldrich Co.) were added and the membranes were incubated at 4°C overnight. On the next day, 1× PBS was used to rinse the membranes for 10 minutes, three times, before they were incubated with Odyssey fluorescent secondary antibodies (1:15,000) in the dark for 1 hour. Subsequently, 1× PBS was used to rinse for 10 minutes, three times. The Tow-color Laser Odyssey Infrared Imaging System (Gene Company Limited, Hong Kong, People’s Republic of China) was used to scan the membranes, and the images were analyzed using Odyssey Version 3.0 software. The ratio of the grayscale value of the target protein to that of β-actin was used for statistical analysis.

Reverse transcription polymerase chain reaction detection of the mRNA levels of Nrf2, HO-1, NF-κB, and TNF-α

Real-time fluorescent quantitative polymerase chain reaction (PCR) was performed to examine the expressions of Nrf2, HO-1, NF-κB, and TNF-α. All primers were synthesized by Beijing Qing Ke New Industrial Biotechnology Co., Ltd. (Beijing, People’s Republic of China), and the primers sequences are shown in Table 1. Reverse transcription PCR (RT-PCR) was performed as follows. The rat was sacrificed at the corresponding time point, and approximately 20 mg brain tissue was rapidly collected on a super-clean bench. TRIzol reagent (Takara Co., Ltd., Dalian City, Liaoning Province, People’s Republic of China) was used for single-step extraction of total RNA, and the RNA quality and concentration were tested at optical density 260/280. Then, 5 μg total RNA was used for reverse transcription reaction with the Real-Time PCR System (Thermo Fisher Scientific, Waltham, MA, USA).

After reverse transcription, all cDNA was diluted to 150 ng/μL, and 2 μL cDNA (diluted) was used for PCR (reagents purchased from Takara Co., Ltd., Dalian City, Liaoning Province, People’s Republic of China [#RR820A]). The cycle threshold was recorded. The results of the real-time quantitative PCR were automatically provided by the quantitative fluorescence analyzer, including the cycle threshold values of the target genes and the reference gene, as well as $\Delta \Delta CT$. Experiments on each group of samples were repeated three times.

Statistical analysis
SPSS 19.0 statistics software was used for data analysis. Data are expressed as means ± standard deviation. For comparison of multiple groups, univariate analysis of variance was performed. For comparison of two groups, the t-test was performed. $P<0.05$ was considered statistically significant.

Results
Magnetic resonance imaging scans of hematomas in rats after ICH
In collaboration with the Radiology Department of Tongji Hospital, affiliated with Huazhong University of Science and Technology and Tongji Medical College, the GE signa Excite HD 3.0 T MR scanner was used to examine the hematomas 3 hours after ICH was established. The scan sequence was as follows: coronal section T2WI, T2*WI, slice thickness 0.8 mm, and interval 0.1 mm. Hematomas were observed in the right basal ganglion (Figure 2).

Neurological score
The neurological deficits of rats in the ICH group peaked on day 3, and on day 7 there was still rather severe damage to the neurological function. On day 1 after surgery, the neurological score of the SFN group was significantly higher than that of the ICH group ($P<0.05$). Compared to the RA group, the neurological function of rats in the SFN group was significantly improved ($P<0.05$). The neurological deficits of rats in the RA group were notably more severe compared to the SFN and ICH groups (Figure 3). The data suggest that SFN intervention after ICH to activate the Nrf2–ARE pathway can significantly alleviate the neurological symptoms of the rats and improve the neurological score. RA inhibits the Nrf2–ARE pathway and aggravates secondary injury after ICH. The Garcia 18-point method was used to evaluate the neurological function of the rats, at 6 hours, 1 day, 2 days, 3 days, and 7 days after surgery.
Coexpression of Nrf2 and HO-1 detected by double immunofluorescence staining

To further investigate the synergistic effect of HO-1 downstream of the Nrf2–ARE signaling pathway on ICH perifocal tissues, coexpression of Nrf2 and HO-1 was examined by double immunofluorescence staining. The 3-day and 7-day subgroups in the SFN group were compared. We found that the cells positive for coexpression of Nrf2 and HO-1 reached a peak on day 3, which suggests that HO-1 may be an important target in neuron protection. The expression of Nrf2 and the downstream target protein HO-1 in the RA group was significantly decreased compared to both the ICH and SFN groups (Figures 4–6).

Figure 3 With time, the neurological dysfunction in rats of the SFN group improved.

Note: *P<0.05 represents the neurological scores in the SFN group or RA group compared to the ICH group.

Abbreviations: DMSO, dimethyl sulfoxide; ICH, intracerebral hemorrhage; RA, retinoic acid; SFN, sulforaphane.

Figure 4 Nrf2 protein and HO-1 protein expression under the immunofluorescence.

Notes: (A) Expression of target proteins in perifocal tissues within 4 mm from the focus of the ICH, as revealed by immunofluorescence staining under low magnification (40×). The yellow box is the target area where the protein expression around the cerebral hemorrhage was observed. (B) Nrf2-positive cells revealed at high magnification (200×). (C) HO-1-positive cells revealed at high magnification (200×). (D) Nuclear staining by 4′,6-diamidino-2-phenylindole (200× magnification). (E) Integration and merged image of panels (A–C) and cell counting using software.

Abbreviations: Nrf2, nuclear factor erythroid 2-related factor 2; ICH, intracerebral hemorrhage; HO-1, heme oxygenase.
Figure 5 Cells stained positive for both Nrf2 and HO-1 protein.

Notes: (A) Cells stained positive for both Nrf2 and HO-1 at 3 days (400× magnification). (B) Cells labeled positive for both Nrf2 and HO-1 at 7 days (400× magnification). In the SFN group, on day 7 the number of cells double-stained for Nrf2 and HO-1 was significantly increased compared to day 3 (P < 0.01). In addition, compared to the RA group, the ICH and DMSO groups had a significantly higher number of cells double-stained for Nrf2 and HO-1 (P < 0.01).

Abbreviations: DAPI, 2-(4-Aminophenyl)-6-indolecarbamidine dihydrochloride; DMSO, dimethyl sulfoxide; HO-1, heme oxygenase; Nrf2, nuclear factor erythroid 2-related factor 2; ICH, intracerebral hemorrhage; RA, retinoic acid; SFN, sulforaphane.
Also, the Nrf2 could coexpress with NF-κB and TNF-α protein. The results indicated that the expression of NF-κB and the Nrf2 protein in the RA group was significantly increased compared to both the ICH and SFN group (Figure S1).

**Nrf2, HO-1, NF-κB, and TNF-α protein expressions revealed by Western blot analysis**

Compared to the ICH group, the expressions of Nrf2 and HO-1 proteins in the DMSO group were not significantly different (P>0.05). Compared to both the SFN and ICH groups, the Nrf2 protein expression in the RA group at 2 days, 3 days, and 7 days (Figure 7) was substantially reduced. After correction for drift by internal reference, we found that these differences were statistically significant.

**mRNA levels of Nrf2, HO-1, NF-κB, and TNF-α revealed by RT-PCR**

RT-PCR results on tissues surrounding the focus of ICH showed that compared to the DMSO and ICH groups, the Nrf2 and HO-1 expressions in the SFN group were both significantly increased, whereas the NF-κB and TNF-α expression were both significantly decreased. Compared to the DMSO and ICH groups, the Nrf2 and HO-1 expression in the RA group were both significantly decreased, whereas the NF-κB and TNF-α expression were both significantly increased (Figure 8).

**Discussion**

Activation of the Nrf2–ARE signaling pathway can induce the expression of endogenous protective genes in a variety of tissues and cells, including antioxidant enzymes, anti-inflammatory factors, and many detoxifying proteins. When these antioxidants and anti-inflammatory factors increase their expression in neurons and glial cells, these cells are protected against the oxidative damages induced by dopamine, glutamate, and hydrogen peroxide.9,10 Activation of inflammatory cells and release of inflammatory cytokines in perifocal tissues after ICH may be crucial to secondary brain damage. The results of the present study showed that RA can inhibit the translocation of Nrf2 into the nucleus, thereby inhibiting the anti-inflammatory effect of the Nrf2–ARE signaling pathway, whereas activation of the Nrf2–ARE signaling pathway by SFN can elevate the expression of the antioxidant enzyme HO-1, thereby reducing the perifocal inflammatory response after ICH and enhancing neuroprotection.
The Nrf2–ARE signaling pathway is a promising new target for the study of the treatment of ICH. Studies have shown that Nrf2 is an important regulator in the antioxidative response of the cells. It interacts with ARE, and plays a wide range of cytoprotective roles in antioxidative, antiapoptotic, and anti-inflammatory responses and neuroprotection. Li and Nel reported that the Nrf2 activator SFN could protect motor neurons by inducing the expressions of HO-1 and quinone oxidoreductase 1. Studies have shown that activation of Nrf2 by SFN can induce microglial activation, enhance phagocytosis of excess iron ions by microglia, and reduce free radicals, thereby playing a neuroprotective role. In addition, it can reduce the inflammatory response induced by lipopolysaccharide (LPS) and decrease the expression of inflammatory cytokines.

The results of the present study showed that SFN activates the Nrf2–ARE signaling pathway, increases Nrf2 and HO-1 expression, and inhibits the expression of perifocal inflammatory substances NF-κB and TNF-α. Comparisons of neurological scores reveal that compared to the ICH group, the protein and mRNA expression of Nrf2 and HO-1 increase, whereas the expression of perifocal inflammatory substances NF-κB and TNF-α decrease in the SFN group. This suggests that the Nrf2–ARE signaling pathway may be involved in the antioxidative and anti-inflammatory responses, inhibition of edema, and neuroprotection in perifocal tissues after ICH. To test our hypothesis further, RA intervention was provided after ICH model was established in the RA group. The results showed that the neurological deficits of the surviving rats were more severe. The data suggest that SFN can activate the Nrf2–ARE pathway and alleviate the neurological symptoms of the ICH rats, which is possibly caused by inhibiting brain edema and the expression of neurotoxic substances. In addition, the protein and mRNA expressions of Nrf2 and HO-1 were both reduced compared to the ICH and SFN groups. Western blot analysis revealed that there was more cytoplasm-bound Nrf2 in the RA than in the SFN group. This suggests that RA inhibits
the dissociation of Nrf2, reduces its translocation into the nucleus, and inhibits the expression of Nrf2 and HO-1. Meanwhile, the perifocal expression of NF-κB and TNF-α is elevated. We demonstrated for the first time that as an Nrf2 inhibitor, the mechanism of the inhibitory effect of RA on the Nrf2–ARE signaling pathway may be through dissociation of Nrf2 and Keap1.

To explore the mechanisms, pathways, key proteins, and key cells underlying the inhibition of the NF-κB inflammatory signaling pathway after ICH by the Nrf2–ARE pathway, double immunofluorescent staining was performed to examine the coexpression of Nrf2 and HO-1 in perifocal tissues. The 1-day, 2-days, 3-days, and 7-days subgroups in the SFN group were compared, and the results revealed that coexpression of Nrf2 and HO-1 reached a peak on day 3 followed by sustained expression until day 7, indicating that HO-1 is located downstream of the Nrf2–ARE signaling pathway, which may be an important target protein in neuroprotection. RA is an Nrf2 inhibitor, the Nrf2 levels were significantly reduced in the RA group compared to both the ICH and SFN groups. HO-1 mediates neuroprotection possibly through the following mechanisms: 1) hemochrome can induce oxidative stress and inflammation, leading to cell damage, and HO-1 plays a detoxifying role by clearing the free hemochromes; and 2) hemochrome is highly lipophilic, upregulates the expression of cell and vascular adhesion molecules, and inhibits the NF-κB signal transduction pathway, thereby playing an anti-inflammatory role. Therefore, in future studies, we would use the specific HO-1 inhibitor zinc protoporphyrin (ZPP)+ to conduct relevant experiments to test the above hypotheses.

Other studies have not shown that activation of Nrf2 can increase the HO-1 expression in microglia. HO-1 can antagonize the effects of LPS-induced TNF-α and interleukin-1 (IL-1) by producing a low concentration of carbon monoxide, and it is a key anti-inflammatory factor that inhibits the macrophage migration factor. The underlying mechanism may be through inhibition of the NF-κB signaling pathway,

**Notes:**
- (A and B) show that compared to the RA and ICH groups, the Nrf2 and HO-1 mRNA expression in the SFN group was significantly elevated (P<0.05); this suggests that SFN induces the translocation of Nrf2 into the nucleus, and enhances the expression of anti-inflammatory protein HO-1 downstream. (C and D) show that compared to the RA and ICH groups, the expression of NF-κB and TNF-α in the SFN group was significantly decreased (P<0.05); this suggests that after the activation of Nrf2 and HO-1 mRNA expressions, anti-inflammatory proteins are expressed. The expressions of various substances in the ICH group in panels (A–D) were not different from that in the DMSO group, suggesting that as a solvent, DMSO does not have any confounding effects. *Statistically significant with SFN and RA.

**Abbreviations:** DMSO, dimethyl sulfoxide; ICH, intracerebral hemorrhage; HO-1, heme oxygenase; Nrf2, nuclear factor erythroid 2-related factor 2; NF-κB, nuclear factor-κB; TNF-α, tumor necrosis factor-α; RA, retinoic acid; SFN, sulforaphane.
inhibition of the dissociation between Inhibitor-KappaB (IxB) and NF-κB, or interference of the nuclear localization signal in the P65 subunit of NF-κB.\textsuperscript{15,16}

NF-κB belongs to the Rel protein family. Typically, it binds to the IxB protein and is localized in the cytoplasm in an inactive form. When cells are stimulated by inflammatory cytokines or chemical substances, NF-κB is dissociated from IxB and enters the nucleus, where it binds to the corresponding target sequence and regulates the transcriptional activity of relevant genes. A variety of factors can activate NF-κB, such as TNF, IL-1, LPS, viral infection, and mitogenic factor. After NF-κB translocates into the nucleus, it binds to NF-κB-binding sites and induces the transcription of the corresponding target genes.\textsuperscript{17–19} The results of the present study showed that NF-κB expression started within 6 hours after ICH, followed by sustained cascade reactions, and in the ICH group, the high expression of NF-κB persisted for 7 days, or even longer. This could produce serious damage to perifocal nerves. In the SFN group, activation of the Nrf2–ARE signaling pathway resulted in inhibition of NF-κB activity on day 3. However, this inhibitory effect gradually declined later on. This result suggests that early activation of the Nrf2–ARE signaling pathway has a neuron-protective effect. These experiments on animal ICH models demonstrate that NF-κB is involved in the pathological process of perifocal injuries after ICH. Meanwhile, the etiology for the elevation of NF-κB expression and its sustained high expression remains unclear. The microglial cells in the central nervous system, which are the safe guards in the system, have both neuroprotective and neurotoxic effects. It remains unclear what regulates the activation and function of microglia. These issues need to be addressed with further studies.

In summary, our results show that SFN activates the Nrf2–ARE signaling pathway to reduce the damage caused by oxidative stress and inflammation and the pathological progress of ICH, and can effectively protect the brain tissues by improving the blood–brain barrier. The Nrf2–ARE signaling pathway serves as a target for ICH treatment at an early stage. This result suggests that early activation of the Nrf2–ARE signaling pathway can serve as a new target for the study on ICH treatment.

**Conclusion**

In conclusion, activation of the Nrf2–ARE signaling pathway by SFN can alleviate the perifocal inflammatory response after ICH, reduce neurological deficits, and increase the expression of the antioxidative enzyme HO-1, and thereby may play a neuroprotective role. The Nrf2–ARE signaling pathway can serve as a new target for the study on ICH treatment.
