Purpose: Although many studies have confirmed the synergic effects of combining chemotherapy (CT) and radiotherapy (RT), clinical data evaluating safety and efficacy of erlotinib in combination with RT in locally advanced non-small-cell lung cancer (NSCLC) are limited. The aim of this study was to determine the feasibility, tolerability, and efficacy of the concurrent addition of erlotinib to the standard three-dimensional conformal thoracic RT in patients with unresectable or locally advanced NSCLC who are not candidates for receiving standard CT.

Patients and methods: Feasibility and tolerability, assessed by evaluating adverse events (AEs), and effectiveness, by calculating progression-free survival (PFS), overall survival (OS), cancer-specific survival (CSS), and objective response rate (ORR), were analyzed in 30 patients receiving RT alone and 60 receiving RT and erlotinib.

Results: Erlotinib with RT showed an extended CSS and a higher rate of complete responses compared with RT alone. No differences between groups were found regarding OS, PFS, and ORR. AEs were significantly higher in the combined treatment, which mainly included cutaneous toxicity, dyspnea, fatigue, hyporexia, diarrhea, and infection. Erlotinib did not increase the toxicity produced by RT.

Conclusion: The combination of erlotinib with RT produced, in our study, a scarce clinical benefit in the treatment of unresectable or locally advanced NSCLC, limited to complete responses and longer CSS rate compared with RT alone. Increased toxicity events were associated with combined therapy, which mainly included cutaneous toxicity. In our opinion, further studies in molecularly unselected lung cancer patients treated with EGFR TKIs and RT are not indicated. The use of biomarkers for the identification of patients that are most likely to benefit from this treatment is an essential next step in the research of this condition.

Keywords: non-small-cell lung cancer, radiotherapy, erlotinib, concurrent

Introduction

Non-small-cell lung cancer (NSCLC) represents the most common type of lung cancer (80%–85%) and is one of the leading causes of cancer-related mortality worldwide.^{1,2} Overall 5-year survival rate is ~15%, but depending on the stage of the disease ranges from 73%, in stage IA, to 2%, in stage IV.³ The majority of patients present with unresectable disease, and ~40% of them in advanced stages.^{4,5} In the last decades, the standard treatment for unresectable or locally advanced NSCLC has varied from single thoracic radiotherapy (RT) to its combination with chemotherapy (CT), ie, chemoradiotherapy.^{6–8} Several trials have shown the higher efficiency, in disease

control and overall survival (OS), of combining both RT and CT with respect to RT alone.^{9–11} Moreover, their concurrent administration has been demonstrated to achieve even better OS rates than the sequential scheme.^{12–14} However, such concurrence of therapies has been associated with higher incidence of grade 3–4 adverse events (AEs), due to increased toxicities. Novel therapeutic agents have been designed to specifically target molecular alterations occurring in NSCLC. Drugs targeting the inhibition of growth factor receptor signaling or angiogenesis have been achieving good clinical outcomes.^{15–17} Erlotinib is an inhibitor of the tyrosine kinase (TKI) activity of the epidermal growth factor receptor (EGFR) that has been approved for patients with advanced NSCLC who failed at least one prior CT regimen. Erlotinib has also been proven to show significant clinical activity in patients with tumors harboring EGFR mutation.¹⁸ Although many studies have confirmed the synergic effects of combining CT and RT,⁶ clinical data evaluating safety and efficacy of erlotinib in combination with RT in advanced NSCLC are currently limited.¹⁹

Therefore, the objective of this study was to determine the feasibility, tolerability, and efficacy of the concurrent addition of erlotinib to the standard three-dimensional conformal thoracic RT treatment in patients with unresectable or locally advanced NSCLC.

Patients and methods

This multicenter, randomized, controlled, open-label, prospective, and nationwide Phase II trial involved patients with unresectable or locally advanced NSCLC. Study design, endpoints, and study assessment are summarized in Table S1.

Eligibility criteria: The criteria for inclusion in the study were: aged over 18 years; histologically confirmed stage IA–IIIB unresectable NSCLC; not susceptible for receiving standard CT; measurable disease; Eastern Cooperative Oncology Group Performance Status (ECOG-PS) 0–2; adequate hematologic, hepatic, renal, and respiratory function; and no previous CT or RT treatment. The main exclusion criteria were: previous CT or RT treatment; previous treatment with erlotinib or any anti-EGFR; any concomitant severe disorder or neoplasia; and pregnancy.

Study design: The control arm (CA) consisted of patients receiving 66 Gy with three-dimensional conformal thoracic RT (5 days/week, conventional fractionation 200 cGy/day), whereas the experimental arm (EA) consisted of patients receiving the same RT dose scheme but combined with erlotinib (150 mg per os [po] for a maximum of 6 months). The rules for tumor delineation in this study were common

to all the participants' hospitals following accepted standard in three-dimensional planning.²⁰ Randomization was centralized, and patients were stratified according to ECOG-PS (0–1 versus 2) and stage of disease (I–II versus III). Primary endpoint was to determine the feasibility and tolerability of the addition of erlotinib to thoracic RT in these patients. The secondary endpoint was to assess the efficacy of the combined treatment, including progression-free survival (PFS), time to progression (TTP), time to treatment failure (TTF), OS, cancer-specific survival (CSS), and objective response rate (ORR). On the basis of primary endpoint and the lack of information concerning the combination of erlotinib and RT, the total number of patients enrolled in the study was 90, ie, 30 in CA and 60 in EA. All patients gave their written informed consent before participating in the study. Procedures were performed in accordance with the guidelines established by the ethics committee of each participating center and the Declaration of Helsinki. This study was approved by the ethics committees of the Hospital of Navarra, Clinical Hospital of Barcelona, Jiménez Díaz Foundation, and University Hospital of Donostia.

Patient evaluation

Total follow-up was calculated from randomization, in March 2006, to the last follow-up visit, in December 2011. Feasibility and tolerability were determined by evaluating the percentage of patients developing grade 3–4 AEs, according to National Cancer Institute-Common Terminology Criteria for Adverse Events NCI-CTCAE v3.0. Complete response (CR), partial response (PR), stable disease (SD), and progressive disease (PD) were assessed using Response Evaluation Criteria in Solid Tumours (RECIST) criteria. No response was defined when PD was observed before tenth week (during RT or just afterward). ORR was calculated as the percentage of patients achieving a CR or PR. Feasibility and tolerability were determined by evaluating the percentage of patients developing grade 3–4 AEs, according to NCI-CTCAE v3.0.

Statistical analysis

Comparisons between groups were assessed using Fisher's exact test. Survival functions were estimated using Kaplan–Meier method (95% confidence interval [95% CI]). A log-rank test was used to compare survival functions between experimental groups. Hazard ratio (HR) was calculated by using the Cox regression model. TTF was calculated as the time from randomization to PD or to treatment discontinuation by any cause. OS was calculated as the time between

randomization to death, or alive (censored), and PFS to disease progression or death, or censored. The CSS was calculated as the time from randomization to death due to PD. Statistical significance was established when $P \leq 0.05$. All the statistical procedures were performed using SAS 9.2 and posteriors.

Results

Patients and tumors at baseline

Demographic and clinical characteristics of patients at baseline are shown in Table S2. All the patients from the CA (N=30) and 90.0% from the EA were male. The median age was 79.8 (interquartile range [IQR]: 74.6–81.2) and 79.3 (IQR: 76.7–81.7) years for CA and EA, respectively. In the CA, approximately half of the patients were smokers (46.7%) and the other half ex-smokers (50.0%). In the EA, 6.7% were nonsmokers, 21.7% smokers, and 71.7% ex-smokers. History of interstitial lung disease was reported in 3.3% and 6.7% of patients from CA and EA, respectively. Most of the patients (60.0% in CA and 63.3% in EA) had ECOG-PS 1 at baseline, while 40.0% and 31.7% had ECOG-PS 2, respectively. The most prevalent tumor stage was IIIB (40.0% versus 38.3% in CA and EA, respectively), followed by IB (20.0% versus 18.3%), IIIA (13.3% versus 16.7%), and IA (13.3% versus 11.7%). Squamous-cell carcinoma was detected in 46.7% of the patients from each group.

The median of treatment duration with RT was 7 weeks. The median total cumulative dose was 66 Gy. Erlotinib was combined concurrently with RT in the EA for a median of 1.8 months (IQR: 1.6–1.8). The median total cumulative dose of erlotinib was 6,850 mg (IQR: 4,825–7,500). The median dose intensity of erlotinib was 0.98 mg (IQR: 0.72–1.00). Erlotinib was maintained in monotherapy after RT in EA for a maximum of 6 months. The median total duration with erlotinib in monotherapy was 17.1 weeks (IQR: 4.1–19.2). The median total follow-up was 15.2 (IQR: 6.3–20.8) and 11.7 months (IQR: 5.7–22.6) in CA and EA, respectively.

Efficacy outcome

The response of tumor to the treatment was evaluated in 78 patients, 28 from the CA (93.3%) and 50 from the EA (83.3%). These responses are summarized in Table 1. CR was achieved in 21.4% versus 41.5% of CA and EA, respectively; PR in 57.1% versus 32.1%; SD in 14.3% versus 11.3%; PD in 3.6% versus 15.1%. Only one patient from the CA (3.6%) showed no response to the treatment. These differences in response rate were statistically significant ($P=0.046$) between

Table 1 Responses of tumor to treatment arms

Responses	RT arm (N=28)	RT + erlotinib arm (N=53)
Tumor responses, n (%)		
CR	6 (21.4)	22 (41.5)
PR	16 (57.1)	17 (32.1)
SD	4 (14.3)	6 (11.3)
PD	1 (3.6)	8 (15.1)
No response	1 (3.6)	0 (0.0)
ORR, n (%)	22 (78.6)	39 (73.6)

Abbreviations: RT, radiotherapy; CR, complete response; PR, partial response; SD, stable disease; PD, progressive disease; ORR, objective response rate.

both the arms. ORR was achieved in 78.6% of the CA and in 73.6% of the EA. The median PFS was 11.4 months (95% CI, 7.5–13.5) in the CA and 8.9 months (95% CI, 6.8–12.9) in the EA (Figure 1). No significant differences were found between both the groups (HR 1.05; 95% CI, 0.66–1.68; $P=0.835$). When considering the type of tumor response, patients from the CA who achieved a CR had a PFS (22.1 months; 95% CI, 2.4–71.4) significantly higher (HR 0.29; 95% CI, 0.08–1.03; $P=0.044$) than patients achieving the remaining of tumor responses (11.4 months; 95% CI, 7.5–13.4). Although patients from the EA with CR had a higher PFS (15.3 months; 95% CI, 10.8–19.5) than the remaining patients (8.0 months; 95% CI, 6.8–12.9), this difference was not statistically significant (HR 0.60; 95% CI, 0.31–1.18; $P=0.134$). The multivariate analysis showed that achieving a CR influenced the PFS rate (HR 0.94; 95% CI, 0.28–0.88; $P=0.017$). TTF was not significantly different (HR 1.49; 95% CI, 0.93–2.38; $P=0.092$) between the CA (11.4 months; 95% CI, 7.5–13.5) and EA (5.2 months; 95% CI, 3.0–7.3). The median OS was 15.3 months (95% CI, 10.1–20.8) in the CA and 12.9 months (95% CI, 8.0–17.2) in the EA. No significant differences were found between both groups (HR 1.18; 95% CI, 0.73–1.92; $P=0.493$). CSS was not significant (HR 0.86; 95% CI, 0.46–1.61; $P=0.645$) between the CA (17.7 months; 95% CI, 11.7–34.7) and EA (21.4 months; 95% CI, 15.0–33.1) (Figure 2).

Safety outcome

The radiation dose was modified in 20.7% of patients from the CA and in 33.3% from the EA. Regarding erlotinib, 26.7% of patients required treatment interruption and 21.7% dose reduction. The main reasons for modifying the dose of erlotinib were: developing an AE (53.1%), improvement from an AE (37.5%), and others (9.4%). Among the 51 patients continuing with erlotinib monotherapy, 27.5% required treatment interruption, 19.6% dose reduction, and

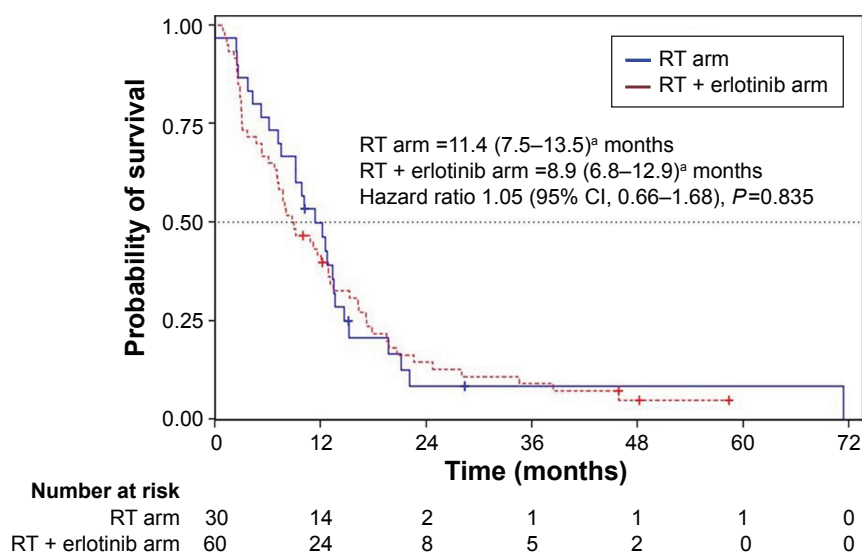

Figure 1 Overall survival for each treatment arm.

Note: ^aData presented as median (range).

Abbreviations: RT, radiotherapy; CI, confidence interval.

17.7% dose escalation. The treatment (RT) was completed in 70.0% of patients from the CA and in 40.0% (whole treatment) from the EA. The reasons for interrupting the treatment were: unacceptable toxicity (0.0% versus 18.3%, respectively), violation of protocol (0.0% versus 2.3%), consent withdrawal (0.0% versus 8.3%), investigator decision (0.0% versus 8.3%), PD (13.3% versus 8.3%), or death (16.7% versus 13.3%). Main AEs developed during the treatment are shown and explained in Table S3.

Cutaneous toxicity was the most frequent AE (66.7% of patients from CA and 86.7% from EA developed at least

one cutaneous event). Cutaneous events included acneiform rash, desquamation, dermatitis, eczema, folliculitis, and radiation skin injury. Grade ≥ 3 rash/desquamation was found in 0.0% versus 13.3% in CA and EA, respectively; radiation skin injury in 3.4% versus 3.3%; and dry skin in 0.0% versus 1.7%. The incidence of developing cutaneous rash was not significantly associated with achieving, or not achieving, a complete tumor response or with ORR. When considering the incidence of cutaneous rash, patients from the EA who developed cutaneous rash had a PFS (11.1 months; 95% CI, 7.7–15.3) significantly higher (*P*<0.0001) than

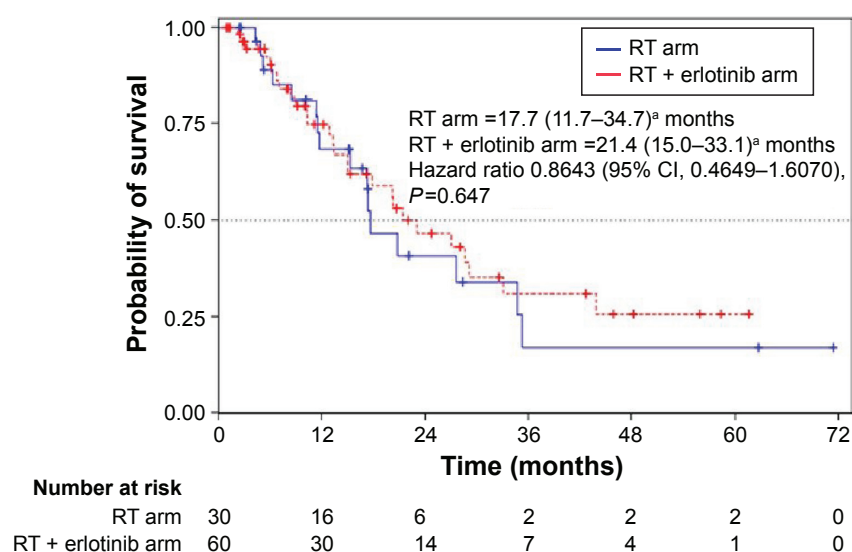

Figure 2 Cancer-specific survival for each treatment arm.

Note: ^aData presented as median (range).

Abbreviations: RT, radiotherapy; CI, confidence interval.

the patients who did not develop it (2.8 months; 95% CI, 1.6–7.3). The multivariate analysis showed that developing cutaneous rash influenced the PFS rate (HR 0.52; 95% CI, 0.28–0.98; $P=0.043$). The association of erlotinib with RT did not increase the cutaneous damage within the irradiation field. The main grade 3–5 AEs reported were the following: dyspnea (13.8% versus 10.0% in CA and EA, respectively), fatigue (0.0% versus 8.3%), hyporexia (3.4% versus 8.3%), diarrhea (3.4% versus 6.7%), and infection (3.4% versus 6.7%). The number of patients with at least one severe AE was significantly higher ($P=0.045$) in the EA (50.0%) when compared to the CA (27.6%). The number of patients with grade 3–5 AEs was significantly higher ($P=0.016$) in the EA (65.0%) compared to the CA (37.9%). Only 21.7% of patients from the EA developed severe AEs caused directly by erlotinib, five patients developed pneumonitis grade 3–5, three (10%) in the CA and two (3.2%) in the EA, but the only patient who died by this cause belonged to the EA. Main AEs observed in the four patients from the EA with history of interstitial lung disease were grade 1–2 fatigue, rash/desquamation, and diarrhea (three patients each), but none presented pneumonitis as AE.

Discussion

RT in combination with CT is the standard for treatment of unresectable or locally advanced NSCLC. Clinical data concerning safety and efficacy of erlotinib when combined concurrently with thoracic RT are currently scarce. Results from our study showed no differences regarding OS, PFS, and ORR. However, erlotinib in combination with RT showed an extended CSS and a higher rate of complete responses, compared with RT alone. By contrast, AEs were significantly higher in the combined treatment, which mainly included cutaneous toxicity.

The combination of RT and CT has been demonstrated to achieve better clinical outcomes, in regard to control of disease and survival rates than RT alone.^{9–11} In 1995, a meta-analysis evaluating data from eleven randomized clinical trials demonstrated that cisplatin-based regimes combined with RT led to a 13% decreased risk of death than RT alone.²¹ Similarly, in 2010, an updated meta-analysis of data from 19 trials showed that the addition of CT to RT decreased the overall risk of death (HR 0.71; 95% CI, 0.64–0.80) and extended the overall PFS (HR 0.69; 95% CI, 0.58–0.81).¹³ Furthermore, a meta-analysis in 2011 compared the effectiveness of concurrent and sequential chemoradiotherapy regimens, and the results indicated that the concurrent scheme improved OS (HR 0.84; 95% CI, 0.74–0.95), presenting an

absolute benefit of 5.7% at 3 years and 4.5% at 5 years.¹² Concomitant to this benefit, the experimental groups with concurrent administration also showed higher incidence of severe AEs, mainly esophageal toxicity.

The efficacy of erlotinib in combination with RT has been extensively evaluated in clinical studies involving patients with different cancer types;^{19,22–24} however, few randomized clinical studies have been performed for NSCLC.²⁵ Indeed, there is no clinical trial to date concerning the safety and effectiveness of erlotinib when administered concurrently with RT. Results from our study showed an extended CSS for the combined therapy (21.4 months) compared with RT alone (17.7 months; not statistically significant), and also a higher rate of complete responses for the combined treatment (41.5%) compared with RT alone (21.4%; statistically significant). Furthermore, patients achieving CR showed higher PFS than other patients (22.1 months in RT alone and 15.3 months in the combined treatment). Additional results from the study showed no differences between groups with respect to OS (15.3 versus 12.9 months in RT alone and the combined treatment, respectively), PFS (11.4 versus 8.9 months), and ORR (78.6% versus 73.6%). Results obtained for the combination therapy of erlotinib with RT were higher than those reported for erlotinib as first-line monotherapy in EGFR-unselected patients.^{18,19} Nevertheless, they are more in accordance with the values reported for patients harboring activating EGFR mutation.¹⁸ A main limitation of the study was the lack of information concerning EGFR mutation from the patients. Although EGFR mutation status has been demonstrated to influence therapeutic results, at the time of our study design, the information published in the literature was not conclusive enough to make the determination of the mutation status in patients mandatory.

In our study, RT alone achieved better clinical outcomes (but not statistically significant) than the concurrent administration with erlotinib. This result might be explained by the characteristics of patients at baseline, ie, with ECOG-PS 2 (31.7% of patients), with tumor stage IIIB (38.3%), with smoking habits (21.7% smokers and 71.7% ex-smokers), and a median age of 79.3 years. The combination of these poor prognosis factors (elderly population, advanced tumor stages, and poor ECOG-PS) might have produced a negative influence on the effectiveness of erlotinib. Some elderly patients with NSCLC are not candidates for CT due to the risk of developing comorbidities.²⁶ For this reason, RT is recommended to be administered alone in patients with locally advanced unresectable tumor who are not candidates for CT or in palliative treatment. These results are consistent with other disappointing

results regarding the lack of benefit when combining cetuximab or erlotinib/gefitinib with RT, such as RTOG 0617, CALGB 30605, and CALGB 30106, in lung cancers.

An increased number of AEs were reported in the combined treatment. In this treatment arm, the main AE developed was cutaneous toxicity (observed in 86.7% of patients). However, erlotinib did not increase the cutaneous damage caused by RT within the irradiation field, and caused neither pulmonary nor esophageal toxicity.

Main grade 3–5 AEs that were noticed were dyspnea (10.0%), fatigue (8.3%), hyporexia (8.3%), diarrhea (6.7%), and infection (6.7%). They were not different from the published ones in other studies with erlotinib. It is interesting to note that in the erlotinib group, the incidence of cutaneous rash was associated with a significant longer PFS (11.1 months), compared with the group having no cutaneous rash (2.8 months). This result is in accordance with previous literature reporting the correlation between the occurrence of cutaneous rash and improved clinical outcomes.²⁷ For this reason, some authors consider cutaneous rash a useful marker for predicting treatment responses in NSCLC.²⁸

Conclusion

In conclusion, the concurrent combination of erlotinib with RT produced, in our study, a scarce clinical benefit limited to CR and longer CSS rate in the treatment of unresectable or locally advanced NSCLC. Although increased toxicity was associated with combined treatment, it was largely manageable. Erlotinib did not increase the toxicity within the irradiation field. Further studies in molecularly unselected lung cancer patients treated with EGFR TKIs and RT are not indicated in our opinion. Use of predictive biomarkers to identify patients most likely to benefit is essential to continue research in this direction.

Primary endpoint	Feasibility and tolerability pattern of the addition of erlotinib to thoracic RT
Secondary endpoint	Efficacy of the combined treatment: <ul style="list-style-type: none"> – Progression-free survival (PFS) – Time to progression (TTP) – Time to treatment failure (TTF) – Overall survival – Cancer specific survival (CSS) – Objective response rate (ORR)
Study arms	<ul style="list-style-type: none"> – Control arm (CA): patients receiving 66 Gy with three-dimensional conformal thoracic RT (5 days/week, conventional fractionation 200 cGy/day) – Experimental arm (EA): patients receiving the same radiotherapy dose scheme but combined with erlotinib (150, 100, or 50 mg po for maximum 6 months)
Number of patients	On the basis of primary endpoint and the lack of information concerning the combination of erlotinib and radiotherapy, the total number of patients enrolled in the study was 90, ie, 30 in the CA and 60 in the EA
Ethics and consent	All patients gave their informed consent before participating in the study. Procedures were performed in accordance with the guidelines established by the ethics committee of each participating center and the Declaration of Helsinki

Abbreviations: NSCLC, non-small-cell lung cancer; ECOG-PS, Eastern Cooperative Oncology Group Performance Status; EGFR, epidermal growth factor receptor; RT, radiotherapy; CT, chemotherapy; po, per oral administration.

Table S2 Demographic and clinical characteristics of patients at baseline

Characteristics	RT arm (N=30)	RT + erlotinib arm (N=60)
Sex, male, n (%)	30 (100.0)	54 (90.0)
Age, median (IQR)	79.8 (74.6–81.2)	79.3 (76.7–81.7)
Smoking habit, n (%)		
Ex-smokers	15 (50.0)	43 (71.7)
Smokers	14 (46.7)	13 (21.7)
Nonsmokers	1 (3.3)	4 (6.7)
History of interstitial lung disease	1 (3.3)	4 (6.7)
ECOG-PS, n (%)		
0	0 (0.0)	3 (5.0)
1	18 (60.0)	38 (63.3)
2	12 (40.0)	19 (31.7)
Tumor stage, n (%)		
IA	4 (13.3)	7 (11.7)
IB	6 (20.0)	11 (18.3)
IIA	1 (3.3)	1 (1.7)
IIB	3 (10.0)	7 (11.7)
IIIA	4 (13.3)	10 (16.7)
IIIB	12 (40.0)	23 (38.3)
IV	0 (0.0)	1 (1.7)
Lung tumor histology, n (%)		
Squamous-cell carcinoma	14 (46.7)	28 (46.7)
Large-cell carcinoma	11 (36.7)	14 (23.3)
Adenocarcinoma	4 (13.3)	12 (20.0)
Others	1 (3.3)	6 (10.0)
Unresectable tumor, n (%)	17 (56.7)	31 (51.7)

Abbreviations: IQR, interquartile range; ECOG-PS, Eastern Cooperative Oncology Group-Performance Status; RT, radiotherapy.

Table S3 Main adverse events related to treatment arms

Adverse events	RT arm (N=29)		RT + erlotinib arm (N=60)	
	AE grade 1–2, n (%)	AE grade 3–5, n (%)	AE grade 1–2, n (%)	AE grade 3–5, n (%)
Cutaneous toxicity				
Rash/desquamation	2 (6.9)	0 (0.0)	34 (56.7)	8 (13.3)
Radiation skin injury	14 (48.3)	1 (3.4)	23 (38.3)	2 (3.3)
Dry skin	0 (0.0)	0 (0.0)	12 (20.0)	1 (1.7)
Fatigue	7 (24.1)	0 (0.0)	27 (45.0)	5 (8.3)
Hyporexia	4 (13.8)	1 (3.4)	23 (38.3)	5 (8.3)
Gastrointestinal				
Diarrhea	2 (6.9)	1 (3.4)	26 (43.3)	4 (6.7)
Mucositis	11 (37.9)	0 (0.0)	18 (30.0)	0 (0.0)
Dysphagia	5 (17.2)	0 (0.0)	9 (15.0)	0 (0.0)
Constipation	0 (0.0)	0 (0.0)	11 (18.3)	0 (0.0)
Vomiting	0 (0.0)	1 (3.4)	8 (13.3)	1 (1.7)
Infection	2 (6.9)	1 (3.4)	6 (10.0)	4 (6.7)
Pulmonary				
Cough	10 (34.5)	0 (0.0)	22 (36.7)	1 (1.7)
Dyspnea	6 (20.7)	4 (13.8)	13 (21.7)	6 (10.0)
Pneumonitis	3 (10.3)	3 (10.3)	9 (15.0)	2 (3.3)
Hematological				
Anemia	3 (10.3)	0 (0.0)	6 (10.0)	2 (3.3)

Note: Main AEs selected occurred in a minimum of ten patients.

Abbreviations: RT, radiotherapy; AE, adverse event.

OncoTargets and Therapy**Dovepress****Publish your work in this journal**

OncoTargets and Therapy is an international, peer-reviewed, open access journal focusing on the pathological basis of all cancers, potential targets for therapy and treatment protocols employed to improve the management of cancer patients. The journal also focuses on the impact of management programs and new therapeutic agents and protocols on

patient perspectives such as quality of life, adherence and satisfaction. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
