Abstract: While clinical trials demonstrate the benefits of blood pressure and cholesterol reduction, medication adherence in clinical practice is problematic. We hypothesized that a single-pill would be superior to a 2-pill regimen for achieving adherence. In this retrospective, cohort study based on pharmacy claims data, patients newly initiated on a calcium channel blocker (CCB) or statin simultaneously or within 30 days, regardless of sequence, were followed (N = 4703). Adherence was measured over 6 months as proportion of days covered (PDC). At baseline, mean age was 63.0 years, 51.6% were female, and mean number of other medications was 7.8. Overall, 16.9% of patients were on single-pill amlodipine/atorvastatin, 15.6% amlodipine + atorvastatin, 24.7% amlodipine + other statin, 13.9% other CCB + atorvastatin, 28.9% other CCB + other statin. Percentages of patients achieving adherence (PDC \geq 80%) were: 67.7% amlodipine/atorvastatin; 49.9% amlodipine + atorvastatin; 40.4% amlodipine + other statin; 46.9% other CCB + atorvastatin; 37.4% other CCB + other statin. After adjusting for treatment selection and cohort differences, odds ratios for adherence with amlodipine/atorvastatin were 1.95 (95% confidence interval [CI], 1.80–2.13) vs amlodipine + atorvastatin, 3.10 (95% CI, 2.85–3.38) vs amlodipine + other statin, 2.06 (95% CI, 1.89–2.24) vs other CCB + atorvastatin, 2.85 (95% CI, 2.61–3.10) vs other CCB + other statin (all $p < 0.0001$). Single-pill amlodipine/atorvastatin may provide clinical benefits through improving adherence, offering clinicians a practical solution for cardiovascular risk management.

Keywords: amlodipine besylate, atorvastatin calcium, adherence, persistence

Introduction

Recent clinical trials and meta-analyses have demonstrated the benefits of antihypertensive and lipid-lowering therapies for the prevention of cardiovascular events (ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group 2002; Sever et al 2003; Staessen et al 2003; Baigent et al 2005) and guidelines support an integrated approach to the reduction of cardiovascular risk (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001). However, few patients receive adequate antihypertensive and lipid-lowering treatment in clinical practice (Wong et al 2006). For example, only 9% of US adults with hypertension and dyslipidemia are at target levels for both blood pressure and low-density lipoprotein cholesterol (Wong et al 2006).

Among the key causes of this treatment gap may be poor patient adherence to cardiovascular medications (Wei et al 2002; Sokol et al 2005; Bramley et al 2006; Burnier 2006; Ho et al 2006; Kulkarni et al 2006). Several studies have observed that patient adherence to antihypertensive and/or lipid-lowering therapy is low (Benner et al 2002; Blackburn et al 2005; Chapman et al 2005). The use of single-pill combination therapy may improve adherence by synchronizing therapies, so that medications are initiated at the same time (Chapman et al 2005; Agarwal et al 2008), and by reducing pill burden (Dezii 2000; Vanderpoel et al 2004; Chapman et al 2005; Gerbino and

Shoheiber 2007) and out-of-pocket costs to the patient (Piette et al 2004; Soumerai et al 2006; Thiebaud et al 2008).

A single-pill therapy combining the antihypertensive medication, amlodipine besylate, and the 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitor (statin), atorvastatin calcium, is the first fixed-dose combination therapy for the treatment of 2 major risk factors for cardiovascular disease (Blank et al 2005). This study sought to test the hypothesis that this single-pill therapy would be superior to a multi-pill antihypertensive and lipid-lowering treatment regimen in the achievement of adherence.

Methods

Study design

This adherence study was a retrospective, longitudinal, cohort study of a diverse, insured, nationally representative US population. Pharmacy claims were used to identify patients using calcium channel blocker (CCB) and statin therapy during the 16-month study period between April 1, 2004 and July 30, 2005.

Data source

This study utilized national pharmacy administrative data from MedImpact Healthcare Systems, Inc. (San Diego, CA, USA) (Sullivan et al 2005; Thiebaud et al 2005, 2006, 2008; Patel et al 2007). MedImpact provides pharmacy benefit management services to plan sponsors, including employer corporations, unions, managed care organizations, health plans, insurance carriers, third-party administrators, as well as local, state, and federal employee programs.

Patient selection

Patients included in the analysis were required to be ≥ 18 years of age and continuously enrolled in a plan sponsor throughout the study period. Patients were newly started on either a CCB or a statin during the study period, and filled prescriptions for both a CCB and statin simultaneously or within 30 days of each other, irrespective of initiation sequence. Five cohorts were specified depending on their CCB and statin therapy: 1. amlodipine/atorvastatin (single pill); 2. amlodipine + atorvastatin; 3. amlodipine + other statin (not including atorvastatin); 4. atorvastatin + other CCB (not including amlodipine); 5. other CCB + other statin (not including atorvastatin or amlodipine). The index date was defined as the first amlodipine/atorvastatin prescription for the single-pill combination cohort. For patients taking CCB + statin treatments as 2 pills, the index date was the prescription claim fill date of the second medication class.

Patients were followed for 180 days from the index date to calculate study outcomes. In an additional analysis, patient adherence at 1 year was evaluated for a subset of patients from the primary analysis who had at least 1 full year of follow-up data. Patients' pharmacy utilization in the 180 days prior to the index date was used to calculate baseline measures such as comorbidity indices.

Patient and regimen characteristics

Age and gender were collected for each patient, as well as several variables describing the patient's pharmacy benefit and medication-taking history, as described below. Business type included commercial managed care organization (MCO), managed Medicare plans, managed Medicaid plans, and self-insured payers. Formulary type defined the pharmacy benefit plan as either open formulary, where all medications are available under a plan sponsor's pharmacy benefit and members would pay a co-payment amount, or a closed formulary, where selected medications are not covered and patients would incur total out-of-pocket cost for these medications. Number of drugs used at baseline was defined by the unique number of medications utilized. Combination tablets including more than 1 drug were only counted as a single medication in this measure. Other specific medications considered at baseline were the continuing study medications (CCB or statin), angiotensin-converting enzyme inhibitors, beta-blockers, diuretics, angiotensin receptor blockers, coronary vasodilators, digoxin, platelet aggregation inhibitors, nitrates, antidiabetic agents, and antidepressants. Adherence patterns at baseline were estimated using prescription use prior to the index date. First DataBank (First DataBank Inc. 2006) classification methodology was used to identify medications for chronic conditions. The prescription claims for these medications are flagged as being either new or refill prescriptions. Using these data, a proxy measure for prior adherence was obtained by calculating: (number of refills)/(number of refills + new claims), where patients with a greater proportion of refills for chronic medications are deemed more compliant at baseline.

Outcomes of interest

The primary outcome of interest was adherence, measured using the proportion of days covered (PDC). The PDC is the proportion of days in the study period that the treatment regimen is available to the patient, as observed from pharmacy claims data (Benner et al 2002; Chapman et al 2005; Ho et al 2006). A 'covered day' for the purposes of the PDC requires the patient to have access to both drugs

on a given day during the observation period (ie, for the 2-pill treatment cohorts, a day covered on both therapies is required). Using this method, in scenarios where an overlap in medication refills exists, the claims and respective days supply were shifted forward in the corresponding amount of overlap. Days supply falling beyond the 180-day study period were truncated and not used in the PDC calculation. For these cohorts, the days supply associated with switching to a different statin or CCB medication was credited to the initial respective study cohorts. Patients were considered adherent if PDC was $\geq 80\%$ (over 180 days for the main analysis, or 360 days for the 1-year analysis) (Benner et al 2002; Chapman et al 2005; Ho et al 2006).

A secondary outcome was non-persistence or discontinuation of therapy, measured as the number of days until the first 30-day gap in therapy (Larsen et al 2002). A sensitivity analysis was undertaken using the medication possession ratio (MPR), calculated as the average of the days supplied with a CCB and the days supplied with a statin divided by the study period (patients were considered adherent if $\text{MPR} \geq 80\%$) (McCombs et al 1994; Halpern et al 2006). It should be noted that the definitions of PDC and MPR for

the measurement of adherence with multiple drugs have not been firmly established in the literature. However, for the purposes of our study, MPR differed to the PDC measurement in that patients did not need to have access to both drugs on the same day to be considered adherent.

Statistical analyses

The primary end point was the adjusted likelihood of achieving 80% adherence with amlodipine/atorvastatin vs other study cohorts. The secondary end point was the adjusted hazard of discontinuing therapies with amlodipine/atorvastatin vs other study cohorts.

Data extraction and statistical analyses were performed using SAS[®] software, Version 9.1.3 (SAS Institute, Inc, Cary, NC, USA). T-tests, F-tests, or Chi-square tests were used to check for differences in baseline characteristics and outcomes between the amlodipine/atorvastatin cohort and all other cohorts. Adjustments for differences as observed in Table 1 were performed using a propensity-score weighting technique to balance treatment groups and address the potential for treatment selection bias due to non-random assignment of treatment by physicians (D'Agostino and Kwan 1995;

D'Agostino 1998; Hirano and Imbens 2001; D'Agostino and D'Agostino 2007; Schneeweiss et al 2008). Propensity score weighting was selected based on a recent comparative simulation that showed this method to be more robust at minimizing bias than other risk adjustment methods, even if the relationship between the observed outcomes and the treatment assignment mechanism was misspecified (Lunceford and Davidian 2004). To apply this method, the propensity score was calculated as the probability of patients receiving each treatment, conditional on the potential confounders listed in Table 1. A propensity score weight was created as the inverse of the propensity score. The primary outcome, odds ratio for achieving adherence $\geq 80\%$, was calculated using logistic regression, controlling for the 15 confounders as well as weighting each observation by the propensity score. Therefore, the propensity score weighting addresses the factors associated with the treatment selection process, and the multivariable logistic regression model measured the effect of treatment on adherence while controlling for baseline confounders.

Adjusted results are presented as the odds ratio (OR) with 95% confidence intervals (CI) for the adherence outcome, and as the hazard ratio (HR) with 95% CI for the persistence outcome. In all analyses differences were considered significant at the level of $p < 0.05$.

Results

Study population

A total of 4703 patients met the study criteria. At baseline, the mean age was 63.0 years, 51.6% of patients were female, 10.7% took nitrate/coronary vasodilators, and 29.6% took antidiabetic medications. The mean number of baseline medications was 7.8. These characteristics varied between the 5 cohorts; patients in the amlodipine/atorvastatin cohort were younger than those in the other cohorts, and more were male. The amlodipine/atorvastatin cohort also appeared to be healthier than other cohorts, utilizing fewer drugs at baseline, eg, a lower proportion received angiotensin-converting enzyme inhibitors, diuretics, coronary vasodilators, digoxin, antidiabetic agents, and antidepressants (Table 1). The majority of all patients were enrolled in an MCO (56.4%–81.0%). Patients in the other CCB + atorvastatin cohort, and those in the amlodipine + atorvastatin cohort were slightly more likely to be Medicaid enrollees, while those patients in the other CCB + other statin cohort were more likely to be Medicare enrollees. Patients receiving amlodipine/atorvastatin were more likely to be enrolled in a self-insured employer population.

Unadjusted mean adherence levels

Pair-wise comparisons of unadjusted mean adherence levels showed significant differences between single-pill amlodipine/atorvastatin and all other cohorts. Adherence for amlodipine/atorvastatin patients was on average 9%–17% higher compared with the other cohorts (Figure 1A). The proportion of patients achieving adherence (PDC $\geq 80\%$) was higher in the amlodipine/atorvastatin cohort than in the other 4 cohorts (Figure 1B).

Adjusted proportion of patients achieving adherence

Adjustments were made for baseline cohort differences using the propensity score weighting models to account for potential treatment selection bias at baseline. Chi-square and ANOVA tests confirmed that the differences between cohorts on the 15 variables were not significantly different following adjustment. After adjustments at 180 days follow-up, patients taking single-pill amlodipine/atorvastatin

Figure 1 (A) Unadjusted mean PDC, and (B) percentage of patients achieving the primary adherence endpoint (PDC $\geq 80\%$) at 180 days' follow-up.

* $p < 0.0001$ amlodipine/atorvastatin vs all other cohorts.

Abbreviations: CCB, calcium channel blocker; PDC, proportion of days covered.

were approximately twice as likely to be adherent as patients taking amlodipine + atorvastatin separately (OR, 1.95; 95% CI, 1.80–2.13, $p < 0.0001$; Figure 2). Additionally, patients taking amlodipine/atorvastatin were between 2.06 and 3.10 times more likely to be adherent than patients taking any of the other 3 drug treatment regimens (amlodipine + other statin, other CCB + atorvastatin, and other CCB + other statin; $p < 0.0001$; Figure 2).

Non-persistence/therapy discontinuation

At 180 days, 71% of single-pill amlodipine/atorvastatin patients remained on therapy in comparison with 61% of patients receiving amlodipine and atorvastatin as separate pills and 50%–59% of patients receiving the other treatment combinations (Figure 3A). After adjusting for covariates, patients taking amlodipine/atorvastatin were 19% less likely to discontinue therapy than those taking atorvastatin + amlodipine separately (HR, 0.81; 95% CI, 0.75–0.87, $p < 0.0001$). Patients in the other 2-pill regimen cohorts were between 22% and 35% more likely to discontinue therapy compared with the amlodipine/atorvastatin cohort (Figure 3B).

Patient adherence after 1 year of therapy

In a subset analysis, patient adherence was evaluated over 1 year among patients who were enrolled for an additional 6 months' follow-up ($N = 3561$; 24% drop in patient count from the original cohort). The baseline characteristics for this subset of patients were comparable to the overall

patient population. At 1 year, in the single-pill amlodipine/atorvastatin cohort, 63.9% of patients achieved adherence. In comparison, the proportion of patients on a 2-pill regimen who were adherent with both antihypertensive and lipid-lowering medications ranged from 33.1% to 43.6%. After adjusting for cohort differences at baseline for this 1-year subgroup, patients given single-pill amlodipine/atorvastatin were found to be approximately 3-times more likely to achieve adherence over 1 year of follow-up (Figure 4).

Sensitivity analysis

In order to determine the effect of the method of measuring adherence used on the observed differences in adherence between patients receiving single-pill amlodipine/atorvastatin and the other treatment cohorts, we conducted a sensitivity analysis for which we used MPR in place of PDC as the measurement of adherence. This analysis found a consistent trend for greater adherence with amlodipine/atorvastatin vs 2-pill CCB + statin regimens at both 6 months (adjusted ORs, 1.19–1.82, $p < 0.0001$) and 1 year (adjusted ORs, 1.59–1.92, $p < 0.0001$). However, the magnitude of the adherence benefit was smaller here than with the PDC measurement.

Discussion

This adherence study demonstrated that patients taking single-pill combination amlodipine/atorvastatin were more likely to be adherent and persistent with therapy compared

with patients taking CCBs and statins as 2 separate pills, over both 6 months and 1 year.

The probability of achieving adherence using single-pill amlodipine/atorvastatin was 1.95-times greater than with the parent compounds amlodipine and atorvastatin administered separately ($p < 0.0001$), and ranged from 2.06- to 3.10-times greater than for any of the other CCB and statin regimens studied ($p < 0.0001$). For the additional 1-year analysis, patients receiving amlodipine/atorvastatin were 2.41- to 3.50-times more likely to achieve adherence than patients on a 2-pill CCB and statin regimen. For the comparison of each of the 2-pill regimen cohorts with amlodipine/atorvastatin, the magnitude of the adherence difference was greater after 1-year follow-up (for those patients remaining on therapy over this time) than at 6 months. Furthermore, patients taking single-pill amlodipine/atorvastatin were less likely to discontinue therapies compared with those taking the parent compounds or other CCB and statin combinations.

The adherence benefit of single-pill amlodipine/atorvastatin may at least in part be due to the reduction in pill burden, and the synchronization of therapy initiation, given that previous observations have shown these factors to increase patient adherence to multiple therapies (Dezii 2000; Vanderpoel et al 2004; Chapman et al 2005; Gerbino and Shoheiber 2007).

In order to achieve maximum benefits in terms of clinical outcomes, it is important that clinicians consider patients' global cardiovascular risk, and address the management

of all coexisting cardiovascular risk factors (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001; Sever et al 2003; Lopez et al 2007). This is reflected in current guidelines and recommendations aimed at reducing the risk of cardiovascular disease in the population (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults 2001). In particular, the use of both antihypertensive and statin therapies for the management of concomitant hypertension and dyslipidemia, or hypertension in the presence of multiple cardiovascular risk factors, is recognized as providing significant benefits for lowering the risk of cardiovascular events (Heart Protection Study Collaborative Group 2002; Sever et al 2003). However, lack of patient adherence to multiple therapies compromises this treatment strategy and is associated with poor clinical outcomes (Benner et al 2002; Wei et al 2002; Blackburn et al 2005; Chapman et al 2005; Sokol et al 2005; Bramley et al 2006; Burnier 2006; Ho et al 2006; Kulkarni et al 2006). As a result, concerns that increasing a patient's pill burden will decrease adherence may discourage physicians from adding further medications to a patient's existing regimen, despite potential therapeutic benefits. The combination of amlodipine and atorvastatin in a single pill may help to allay such concerns with regard to the addition of statin therapy in hypertensive patients with high cardiovascular risk, or an antihypertensive in those with elevated blood pressure who are already receiving a statin. In support of this, the present study provides preliminary

indications that single-pill amlodipine/atorvastatin may help address issues of poor adherence to antihypertensive and lipid-lowering medications. Additional studies assessing whether increased adherence and persistence with single-pill amlodipine/atorvastatin translates to improved attainment of blood pressure and lipid goals and, more importantly, a reduced incidence of cardiovascular events and improved health outcomes for the patient, are warranted.

The study limitations include the potential for bias that may have occurred due to the retrospective and non-randomized nature of the design, and that possible drug treatment selection bias may not be fully taken into account by the propensity weighting methodology used. However, Chi-square and ANOVA tests of differences between cohorts on the 15 independent variables used for adjustment found no significant differences after adjustment methods were applied. Indications for single-pill amlodipine/atorvastatin may include an expected lack of adherence to medications, which may be a confounding factor in this analysis, although previous adherence patterns were included as a covariate for propensity score weight. In addition, while patients in the single-pill cohort were younger, took fewer baseline medications, and were more likely to be enrolled in an MCO than in the other cohorts (characteristics which could potentially influence the likelihood of being adherent) these factors were also adjusted for in the proportional hazards analysis. Limited variables were available due to the lack of data related to medical diagnoses and severity of illness.

Other important confounding factors that could not be considered in this administrative claims analysis are the quality of care, intensity of counseling, patient's perception and beliefs towards the effectiveness of treatment (ie, potential for self-efficacy), the health care resources available, and the effect on clinical end points (eg, blood pressure and cholesterol). However, this study was specifically designed to assess differences in observed adherence between treatment regimens in a real-world setting, and was not intended to assess the influence of these other factors.

Assessing adherence based on prescription refill rates is a proxy measure only and a patient's true pattern of medication taking may still be unknown. In addition, the timing of prescription refill patterns was assumed to correlate with medication consumption, which may amplify the magnitude of adherence differences observed using PDC vs MPR. However, it has been noted that most studies of the validity of prescription refill rates have shown that measures of prescription refill rates are significantly associated with other

measures of adherence, serum drug levels, or physiologic drug effects (Steiner and Prochazka 1997). The observed benefits on adherence of single-pill amlodipine/atorvastatin compared with 2-pill CCB and statin regimens were consistent with the sensitivity analysis using the MPR as an alternative method of measuring adherence, although the magnitude of the difference was lower.

Despite the limitations detailed above, the benefits on adherence of single-pill amlodipine/atorvastatin compared with a 2-pill CCB and statin regimen were robust in that they were observed using 2 methods of measurement (PDC and MPR), at 2 points in time, and are consistent with the evaluation of persistence. Given the high level of significance observed in these comparisons, additional statistical adjustments for multiple comparisons were not necessary as they would have remained significant under such adjustments.

Following the findings from this study, physicians who prescribe antihypertensive and lipid-lowering therapies for the management of cardiovascular risk should consider the potential benefits of therapy adherence that may be afforded by a single-pill, such as amlodipine/atorvastatin, as a means of simplifying their patient's treatment regimen, reducing pill burden, and synchronizing antihypertensive and statin therapy (Bangalore et al 2007). Single-pill amlodipine/atorvastatin therapy provides a potential opportunity for improving adherence over a multi-pill treatment regimen, although further studies are required to determine whether this will result in improvements in therapeutic goal attainment and patients' long-term clinical outcomes, and in lower health-service utilizations.
