Thailand

Objectives: To compare the effect of peritoneal gas drain on postoperative pain in benign gynecologic laparoscopic surgery and the amount of postoperative analgesic dosage.

Methods: The trial included 45 females who had undergone operations during the period December 2014 to October 2015. The patients were block randomized based on operating time (<2 and ≥ 2 hours). The intervention group ($n=23$) was treated with postoperative intraperitoneal gas drain and the control group ($n=22$) was not. The mean difference in scores for shoulder, epigastric, suprapubic, and overall pain at 6, 24, 48 hours postoperatively were statistically evaluated using mixed-effect restricted maximum likelihood regression. The differences in the analgesic drug usage between the groups were also analyzed using a Student's *t*-test. The data were divided and analyzed to two subgroups based on operating time (<2 hours, $n=20$; and ≥ 2 hours, $n=25$).

Results: The intervention had significantly lower overall pain than the control group, with a mean difference and 95% confidence interval at 6, 24, and 48 hours of 2.59 (1.49–3.69), 2.23 (1.13–3.34), and 1.48 (0.3–2.58), respectively. Correspondingly, analgesic drug dosage was significantly lower in the intervention group (3.52 ± 1.47 mg vs 5.72 ± 2.43 mg, $P < 0.001$). The three largest mean differences in patients with operating times of ≥ 2 hours were in overall pain, suprapubic pain at 6 hours, and shoulder pain at 24 hours at 3.27 (1.14–5.39), 3.20 (1.11–5.26), and 3.13 (1.00–5.24), respectively. These were greater than the three largest mean differences in the group with operating times of <2 hours, which were 2.81 (1.31–4.29), 2.63 (0.51–4.73), and 2.02 (0.68–3.36). The greatest analgesic drug requirement was in the control group with a longer operative time.

Conclusion: The use of intraperitoneal gas drain was shown to reduce overall postoperative pain in benign gynecologic laparoscopic surgery. The effects were higher in patients who had experienced longer operating times.

Keywords: laparoscopic surgery, intraperitoneal gas drain, postoperative pain, gynecology

Introduction

Operative gynecologic laparoscopy is becoming the primary approach for treatment of benign gynecologic diseases, as it is a less invasive procedure and can help shorten the length of hospitalization.^{1,2} Most complications occur during abdominal access or port placement, while other complications arise during abdominal insufflations, tissue dissection, and homeostasis.^{3,4} However, postoperative pain at the shoulder and upper abdomen has been shown to be the most common complaint in many studies. It has been hypothesized that this is due to CO₂ residue, which causes stretching of the postdistended diaphragm and peritoneum after prolonged surgery.^{5–7} The suprapubic pain comes directly from the surgical wound, which is also affected by postoperative abdominal distension.

Several methods have been recommended to improve postoperative pain for ambulatory procedures, including a pulmonary recruitment maneuver,^{8,9} intraperitoneal infusion with saline¹⁰ or analgesic drugs,¹¹ low pressure laparoscopic surgery,¹² and the prescription of different types of preoperative medicine.¹³

Studies have shown peritoneal gas drain to be a procedure that could potentially be used to alleviate postoperative pain. Many previous studies have reported good results from using this procedure.^{5,7,14,15} Recently, a systematic review mentioned that there was little evidence to support the effectiveness of intraperitoneal gas drain in reducing postoperative pain.¹⁶

This paper was, thus, designed as a block-randomized double-blinded controlled trial to determine whether or not peritoneal gas drain would be able to relieve shoulder, epigastric, suprapubic, and overall postoperative pain and also to evaluate potential differences among subgroups categorized by surgical procedure duration.

Materials and methods

This study was conducted at Srinagarind Hospital, Faculty of Medicine, Khon Kaen University from December 2014 to October 2015. Patients 18 years and older with benign gynecologic conditions for whom laparoscopic surgery was indicated were recruited. A signed consent form was obtained from all patients after they were counseled about surgical procedures, possible complications, details of the gas drain procedure, and the pain-assessment process. Routine preoperative medications administered were 1 g of acetaminophen orally and 50 mg of ranitidine intravenously. Nitrous oxide, oxygen, sevoflurane, cisatracurium, and morphine were administered as anesthetic drugs during surgery. Dexamethasone (4–8 mg), ondansetron (8 mg), and diclofenac (75 mg) were used during the recovery period to prevent postoperative nausea and vomiting.

All the operations were performed by an experienced gynecologic laparoscopist. Just before finishing the operation, the patients were assigned to either the intervention or control group using block randomization of sealed envelopes separated by operating time (<2 and ≥2 hours).

In the intervention group, a No 14 nasogastric tube (Zuellig Pharma, Bangkok, Thailand) was inserted 10 cm into the peritoneal cavity before closure of the patient's abdominal wall. In the control group, the drain tube was simply inserted under a strip of sterile gauze and there was no intraperitoneal insertion. In both groups, the external area was bandaged and connected to a sterile plastic bag after the operation.

The evaluator, a well-trained member of the nursing staff, who was blind to the procedure, was assigned to evaluate the pain level by using a visual analog scale at 6, 24, and 48 hours after the operation. After the assessment at 6 hours, a training resident was assigned to remove the drain tube. The evaluator remained blind to the process. If the patient felt pain at any time, up to 3 mg of morphine at 4-hour intervals would be administered intravenously as needed, as described in diagram flow (Figure 1).

Preoperative data, including age, parity, body mass index, prior abdominal surgery, preoperative diagnosis, and intraoperative data, including duration of operation and estimated blood loss were recorded, as well as postoperative data, including complications, postoperative diagnosis, and length of hospital stay.

This study was approved by the Khon Kaen University Ethics Committee No HE571349.

Statistical method and analysis

The sample-size calculation was conducted using a repeated measurement calculator formula with a type I error of 1% and 80% power, resulting in each group consisting of 22 patients. A clinically significant difference would be determined if a three-point difference in visual analog scores was found. Percentage, mean, and standard deviation are described in the demographic data. Mixed-effect restricted maximum likelihood regression was used to evaluate statistical differences in the pain scores, and a Student's *t*-test was used to compare for analgesic usage. All statistical analyses were calculated using the Stata program Version 10.1 (StataCorp LP, College Station, TX, USA).

Results

Forty-five patients (intervention group, N=23 and control group, N=22) were recruited for this study. There were no statistically significant differences between the two groups in age (39.56 ± 9.85 vs 38.86 ± 9.76 , $P=0.405$), body mass index, parity, surgical history, estimated blood loss, operating time, and pathological diagnosis (Tables 1 and 2). The pain scores of the intervention group were significantly lower at all parameters, with the exception of epigastric pain at 48 hours (mean difference 0.8, 95% confidence interval [CI] -0.23 to 1.83). The two largest differences in mean pain scores between the groups were in the suprapubic and overall pain at 6 hours, 2.92 (95% CI 1.86–3.98) and 2.59 (95% CI 1.49–3.69) (Figure 2). No major postoperative

Figure 1 Diagram flow.

Abbreviation: MO, morphine.

complications were detected in either group, and all patients were discharged on the third day after the operation.

There were 25 patients in the operating time ≥ 2 hours subgroup (intervention, N=13; and control, N=12), and 20 patients in the operating time < 2 hours subgroup, (intervention and control, N=10). There was no statistically significant difference in operating times between the subgroups in the intervention and the corresponding control group (Table 2).

In the ≥ 2 hours subgroup, the intervention group showed significantly reduced overall scores at 6, 24, and 48 hours with mean differences 3.27 (95% CI 1.14–5.39), 2.43 (95% CI 0.72–4.14), 1.65 (95% CI 0.39–2.90), respectively. This group also showed improvements in other parameters, as shown in Figure 3. The mean differences in shoulder pain scores at 6, 24, and 48 hours were especially better in the

intervention group at 2.11 (95% CI –0.30 to 4.51), 3.13 (95% CI 1.00–5.24), and 2.40 (95% CI 0.70–4.08), respectively.

In the < 2 hours subgroup, the intervention group showed better overall pain scores at 6, 24, and 48 hours, with lesser mean differences compared to the long operation group (Figure 3) at 1.81 (95% CI –0.01 to –3.63), 2.02 (95% CI 0.68–3.36), and 1.28 (95% CI 0.28–2.26), respectively. Suprapubic pain was a parameter that showed significant difference in the intervention group at 6, 24, and 48 hours (Figure 3).

In the operating time ≥ 2 hours subgroup, overall pain at 6 hours, suprapubic pain at 6 hours, and shoulder pain at 24 hours showed the largest mean difference at 3.27 (95% CI 1.14–5.39), 3.20 (95% CI 1.11–5.26), and 3.13 (95% CI 1.00–5.24), respectively. These were higher than the three largest mean differences in operating time < 2 hours

Discussion

This paper showed that the postoperative intra-abdominal tube drain could be an effective method for improving postoperative pain at nearly all parameters. The best results were recorded when using it after laparoscopic surgery lasting >2 hours. The reduction in the amount of morphine required in the group with operating times ≥ 2 hours was also greater than those with operating times <2 hours. The ≥ 2 hours subgroup showed the greatest improvement with regard to shoulder pain, while in the <2 hours subgroup, the greatest improvement was in pelvic pain reduction.

The hypothesis was that, compared to shorter procedures, postoperative subdiaphragmatic stretching by residue CO₂ after prolonged surgery (≥ 2 hours) might cause more inflammation and shoulder pain, which would cause the patient to experience significant pain reduction from the gas drain. In contrast, in a shorter operation (<2 hours), the suprapubic pain, which came directly from the surgical wound, was dominant compared to the shoulder pain and was also significantly reduced by the gas drain. Recently, there have been many studies of laparoscopic cholecystectomy that have yielded conflicting results.^{14,15,17} In these studies, pain scores in the intervention groups were higher than those in the control groups. The intervention groups also had higher rates of complications such as infection and prolonged hospitalization. These results could be explained by the duration of the drain lasting at least 24 hours, the use of an active gas drain, or the type of surgery. Cholecystectomy, which takes place near the diaphragm, causes more inflammation and may result in more postoperative shoulder pain.

In a systematic review, Craciunas et al¹⁶ concluded that there was little evidence to support the use of intraperitoneal gas drain in reducing postoperative pain and suggested that future study was required to minimize the bias resulting from operating time and using the analgesic dosage as an objective measure for pain evaluation. We, thus, conducted this study according to those guidelines.

The strength of this study was that it was a block-randomized double-blinded controlled trial, which controlled for operating

time between both groups. Furthermore, the operations were performed by one surgeon to control for operation bias. The main limitation of this study was the small subgroup sample size, especially in the ≥ 2 subgroup. Further studies with larger sample sizes are recommended.

Although there are many methods to reduce postoperative pain in ambulatory laparoscopy,^{7–10,13,18} it is our opinion that the more complicated the laparoscopic procedure is, the longer would be the duration of surgery and hospitalization required. In addition, laparoscopic equipment will become increasingly smaller in diameter over the next decade, causing difficulty in CO₂ reduction before the port suture, and then this procedure will help to prolong the duration of gas release. However, this easy and safe procedure can also be conducted in conjunction with methods mentioned above.

Conclusion

The use of intraperitoneal gas drain could significantly improve postoperative pain in benign gynecologic laparoscopic surgery. We recommend using this procedure postoperatively, especially in cases of long operating times.
