Psoriasis: Targets and Therapy

Pustular psoriasis: pathophysiology and current treatment perspectives

Abstract: Psoriasis vulgaris is a chronic inflammatory disease that classically affects skin and joints and is associated with numerous comorbidities. There are several clinical subtypes of psoriasis including the uncommon pustular variants, which are subdivided into generalized and localized forms. Generalized forms of pustular psoriasis include acute generalized pustular psoriasis, pustular psoriasis of pregnancy, and infantile and juvenile pustular psoriasis. Localized forms include acrodermatitis continua of Hallopeau and palmoplantar pustular psoriasis. These subtypes vary in their presentations, but all have similar histopathologic characteristics. The immunopathogenesis of each entity remains to be fully elucidated and some debate exists as to whether these inflammatory pustular dermatoses should be classified as entities distinct from psoriasis vulgaris. Due to the rarity of these conditions and the questionable link to the common, plaque-type psoriasis, numerous therapies have shown variable results and most entities remain difficult to treat. With increasing knowledge of the pathogenesis of these variants of pustular psoriasis, the development and use of biologic and other immunomodulatory therapies holds promise for the future of successfully treating pustular variants of psoriasis.

Keywords: psoriasis, pustular psoriasis, generalized pustular psoriasis, von Zumbusch, impetigo herpetiformis, acrodermatitis continua of Hallopeau, palmoplantar pustulosis, biologic

Introduction

Psoriasis vulgaris is a chronic inflammatory condition associated with significant morbidity and mortality.1 Plaque psoriasis is the most common form of psoriasis vulgaris and classically presents as discrete, erythematous plaques with an overlying silvery scale on extensor surfaces. Psoriasis can also involve the nails and scalp or progress to erythroderma. Less common clinical presentations include guttate, inverse, or pustular psoriasis.2

Within the classification of pustular psoriasis, the disease is further subdivided into generalized pustular psoriasis (GPP) and localized pustular psoriasis. GPP includes acute GPP, pustular psoriasis of pregnancy, and infantile/juvenile pustular psoriasis. Localized pustular psoriasis includes palmoplantar psoriasis and acrodermatitis continua of Hallopeau (ACH).2–5

All variants of pustular psoriasis have similar presentations in that they involve an eruption of superficial pustules in a given distribution, typically with an erythematous base or studded on a background of erythema. As such, histopathologic examination of all variants reveals parakeratosis, extensive mononuclear and neutrophilic inflammatory infiltrate in the epidermis, and epidermal edema and hyperplasia.5–10 Spongiform...
pustules of Kogoj and hyperplasia of suprapapillary capillaries may be seen.\textsuperscript{5,11–13} Munro’s microabscesses typical of plaque psoriasis are frequently seen as well.\textsuperscript{13}

**Generalized pustular psoriasis**

**Acute GPP (von Zumbusch type)**

**History**

Acute GPP, also known as von Zumbusch type, is a dermatologic disease for which classification is somewhat debated.\textsuperscript{14} Sixty-five percent of cases of acute GPP occur in patients with a prior diagnosis of psoriasis vulgaris,\textsuperscript{15,16} and historically, acute GPP has been presented as a variant of plaque psoriasis. However, recent research indicates that acute GPP and plaque psoriasis are genetically distinct conditions without a common pathophysiologic mechanism.\textsuperscript{17}

**Epidemiology/presentation**

Acute GPP is associated with significant morbidity and in some cases, mortality, especially in the absence of appropriate treatment.\textsuperscript{16} It is characterized by generalized sterile pustule formation with widespread inflammation and erythema (Figure 1). The pustules often expand and coalesce, forming lakes of pus.\textsuperscript{1} Acute GPP is often associated with systemic symptoms such as fever, chills, malaise, anorexia, nausea, and severe pain.\textsuperscript{1,18} Other physical findings may be present with acute GPP, such as subungual pustules and geographic tongue.\textsuperscript{1} The systemic nature of the disease is reflected in the laboratory abnormalities found in many patients, including hypocalcemia and hypoalbuminemia, as well as in the possible presence of polyarthralgias and neutrophilic cholangitis-induced cholestasis.\textsuperscript{19,20}

The mean age at onset of acute GPP is 40.9 years, with no difference in onset related to the presence or absence of a prior history of psoriasis vulgaris.\textsuperscript{15} Two separate studies have found a higher incidence of acute GPP in male, with an incidence of 57\%–62\%.\textsuperscript{16,20} The majority of studies, however, found a predominance in female, ranging from 53\% to 73\%.\textsuperscript{15,19,21,22} Females do tend to have a nonstatistically significant earlier onset compared to male, with a mean age of 39.4 years compared to 44.3 years.\textsuperscript{15}

**Pathophysiology**

Various precipitating factors have been reported to trigger or flare acute GPP, including corticosteroid use and withdrawal, pregnancy (also termed impetigo herpetiformis), upper respiratory tract infections, stress, nonsteroidal anti-inflammatory drugs, terbinafine, ustekinumab, tumor necrosis factor (TNF)-\(\alpha\) inhibitors, and methotrexate.\textsuperscript{12,23}

The use and subsequent withdrawal of systemic corticosteroids is an important cause of an eruption of acute GPP.\textsuperscript{24} The use of systemic corticosteroids leads to inhibition of the inflammatory system. Acute withdrawal of systemic corticosteroids can lead to an acute inflammatory process acting as a trigger for acute GPP.\textsuperscript{12} In one retrospective study of 102 patients with acute GPP, systemic glucocorticoids were determined to be a likely trigger for the onset of the disease in 44\% of patients.\textsuperscript{15}

Upper respiratory tract infections, and other infections, can also lead to an acute activation of neutrophils, which may act as a trigger for the onset of acute GPP.\textsuperscript{12} Choon et al\textsuperscript{15} reported that acute infections have been found to be a trigger or exacerating factor in 16\% of acute GPP patients, with 38.5\% of patients exhibiting positive antistreptolysin antibodies. Ustekinumab, a monoclonal antibody against the p40 subunit common to interleukin (IL)-12 and IL-23, which is commonly used for the treatment of plaque psoriasis, can lead to a change in a patient’s psoriasis morphology from plaque psoriasis to pustular psoriasis and can also cause new or worsening acute GPP.\textsuperscript{25,26} Other drugs, such as terbinafine and methotrexate, may also serve as triggers for acute GPP as a form of drug-specific allergic reactions, which can often be confirmed with patch tests.\textsuperscript{12,27}

GPP may also be strongly associated with certain predisposing genetic factors. In a study of nine Tunisian families with GPP, a genetic mutation in the \(IL36RN\) gene leading to an aberrant IL-36 receptor antagonist (IL-36RA) was discovered in all affected patients in the study and was noted to cause an unstable IL-36RA protein with decreased affinity for its receptor.\textsuperscript{28} The mutation in the IL-36RA protein also
Psoriasis: Targets and Therapy downloaded from https://www.dovepress.com/ by 54.70.40.11 on 12-Jan-2020
For personal use only.

In recent years, additional reports of biologic therapies targeting IL-1, IL-12/23p40, and IL-17A have been reported.

Acute GPP has proven to be, like many psoriasis variants, a difficult disease to treat. Guidelines published in 2012 by the Medical Board of the National Psoriasis Foundation recommend acitretin, cyclosporine, or methotrexate to be the first-line therapies for acute GPP (Table 1). Severe and extensive disease is likely to most effectively be treated with infliximab or cyclosporine, given the quicker onset of action with these drugs. Infliximab, a TNF-α inhibitor, has a uniquely rapid onset of therapeutic effect. One study described the efficacy in nine of ten patients with acute GPP who experienced results within 24 hours to 7 days of the first treatment. A similar study showed an improvement in all patients with acute GPP at 2 weeks following initiation of infliximab therapy, with disappearance of pustules in all enrolled patients and continued remission at 30 weeks. The recommended second-line therapies include adalimumab, etanercept, psoralen plus ultraviolet-A (PUVA) phototherapy, topical corticosteroids, topical calcipotriene, and topical tacrolimus, or combination therapy for recalcitrant disease (which includes a first-line oral systemic agent plus a biologic agent such as adalimumab or etanercept). The initial use of infliximab to treat severe acute disease, followed by treatment with etanercept has also been reported to be successful. The use of systemic steroids is generally avoided when treating pustular psoriasis, given the risk of worsening disease following withdrawal of the medication. If necessary, however, they may be used in circumstances in which other therapeutic options are not available.

In recent years, additional reports of biologic therapies targeting IL-1, IL-12/23p40, and IL-17A have been reported.

Anakinra, an IL-1 receptor antagonist, has been described to successfully treat GPP, and gevokizumab, an IL-1β inhibitor, showed some promise in treating two patients with GPP. The unique treatment of GPP with granulocyte and monocyte adsorption apheresis (GMA) apheresis has also been described. Because the immunopathogenesis of GPP involves activated neutrophils and monocytes, GMA provides an effective treatment that involves removal of activated granulocytes and monocytes from the patient’s circulation, resulting in improvement of acute GPP. 46–48 49

46–48 The unique treatment of GPP with granulocyte and monocyte adsorption apheresis (GMA) apheresis has also been described. Because the immunopathogenesis of GPP involves activated neutrophils and monocytes, GMA provides an effective treatment that involves removal of activated granulocytes and monocytes from the patient’s circulation, resulting in improvement of acute GPP. 46–48 49

Despite reports of successful treatment of acute GPP with various biologic agents, the literature supporting the
treatment of acute GPP is weak. Further exploration with larger, randomized, controlled studies of biological medications in the treatment of acute GPP are needed in order to determine its efficacy and safety on a larger scale.

Pustular psoriasis of pregnancy

History

The pustular dermatitis, known today as pustular psoriasis of pregnancy, was first described in 1872 by von Hebra using the term “impetigo herpetiformis”. Later, clinical and historical studies of patients with impetigo herpetiformis led to the discovery of similarities between this entity and pustular psoriasis. However, the classification of this dermatitis as a disease distinct from pustular psoriasis is still debated, and in various studies, it continues to be discussed as impetigo herpetiformis.

Epidemiology/presentation

Pustular psoriasis of pregnancy is a rare autoimmune inflammatory dermatosis observed most commonly in the second half to third trimester of pregnancy. Some publications, however, report the occurrence as early as the first month of pregnancy. The true incidence of pustular psoriasis of pregnancy is unknown owing to the paucity of published cases. Patients typically present with an eruption of numerous sterile pustules overlying annular or polycyclic erythematous patches, with lesions usually beginning within skin folds and spreading radially. The face, palms, and soles are largely spared. Constitutional symptoms may also be present, including fever, chills, malaise, nausea, diarrhea, dehydration, arthralgias, and even tachycardia and seizures. Common lab findings include leukocytosis with a neutrophilic predominance, anemia, increased erythrocyte sedimentation rate, as well as hypocalcemia, hypophosphatemia, hypoalbuminemia, and decreased vitamin D levels in some cases. In reports of more severe disease, hypocalcemia which led to tetany, delirium, and convulsions was observed.

The presence of pustular psoriasis of pregnancy has been historically associated with poor neonatal outcomes including placental insufficiency, stillbirth, fetal abnormalities, and early neonatal death, with a correlation between severity and duration of the disease and poor neonatal prognosis. Maternal death has also been reported. Given this correlation, patients who present with severe or recalcitrant pustular psoriasis of pregnancy are often counseled regarding early induction of labor. Following delivery, many patients have dramatic and rapid resolution of their dermatologic disease. However, recurrence of disease in subsequent pregnancies is common.

Pathophysiology

The pathophysiology of pustular psoriasis of pregnancy is even more elusive than in other forms of pustular psoriasis, which is likely due to the low incidence of the disease. Female with pustular psoriasis of pregnancy seldom report a personal or family history of psoriasis; but in some cases, resolution of the acute pustular form of the disease results in lingering classic psoriatic lesions. As mentioned, an association between this disease in pregnant female and hypocalcemia or low serum vitamin D levels may be present, but these lab findings are not evident in all patients and there is no evidence to support causality of these abnormal lab values.

Literature on the theoretical pathogenesis of pustular psoriasis of pregnancy typically discusses possible triggers associated with development of the disease. Potential triggers include increasing levels of progesterone during the last trimester of pregnancy, hypocalcemia, and lower levels of elastin, an epidermal skin-derived antileukoproteinase, which may all contribute to the production of epidermal pustules. Associations with hormonal contraception, increased stress levels, seasonal changes, concurrent bacterial infections, and certain medications have been described. There have also been reports of the association between pustular psoriasis of pregnancy and hypothyroidism.

Another important consideration in defining the theoretical pathogenesis of pustular psoriasis of pregnancy involves specific situations in which patients suffer from an acute eruption or worsening of GPP during pregnancy. Pregnancy has been noted as a precipitating factor for the new development or acute flare of GPP.

Treatment

Patients should be assessed by their obstetrician for potential early induction of labor as the first and best therapeutic option for this disease. In terms of therapeutic options, systemic corticosteroids are widely accepted to be the most commonly used first-line treatment for pustular psoriasis of pregnancy (Table 2). Robinson et al developed a treatment algorithm for GPP in pregnancy, which included ciclosporine, infliximab, topical corticosteroids, and topical calcipotriene as the first-line treatment options, in addition to systemic prednisone. Case reports regarding the successful use of ciclosporine in this disease are present in the literature.

Infantile and juvenile pustular psoriasis

While psoriasis is a common disease in children and adolescents, pustular psoriasis in patients younger than 18 years is exceedingly rare. There are only a few reports in the literature regarding pustular psoriasis in children, owing to its rarity. One report reviewing 12 cases of juvenile pustular psoriasis indicates a 2:1 male predominance. The average age of onset ranges from 6.6 to 7.6 years. The diagnosis is typically made based on clinical and histological features. Clinically, juvenile pustular psoriasis can present in a diffuse generalized pustular pattern similar to adult GPP, or more commonly, it can present in a circinate or annular pattern. The affected children often have systemic findings including fever, as well as lab abnormalities such as leukocytosis and elevated erythrocyte sedimentation rate.

The etiology and pathogenesis of juvenile pustular psoriasis are unknown. The disease has been reported in several sibling or other familial associations, lending to the theory of at least a partial genetic component to the dermatosis. Juvenile pustular psoriasis, like other forms of psoriasis, is often associated with identifiable triggers such as infection, vaccination, and corticosteroid withdrawal.

**Treatment**

The rarity of pustular psoriasis in children has also led to a lack of evidence-based treatment literature. The Medical Board of the National Psoriasis Foundation has published guidelines on the treatment of pustular psoriasis in children. First-line therapy for this disease is similar to that of pustular psoriasis in adults. Acitretin, cyclosporine, etanercept, or methotrexate can each be used safely as first-line therapeutic options in children with pustular psoriasis. Second-line therapeutic options include adalimumab, infliximab, and UVB phototherapy. Juvenile pustular psoriasis...
Pustular psoriasis

Localized pustular psoriasis

Palmoplantar pustular psoriasis

History

Palmoplantar pustular psoriasis (PPP), also known as palmoplantar pustulosis, is a form of localized pustular psoriasis on the palms and/or soles. This entity was first described in 1888 by Crocker with the name “dermatitis repens”. The classification of palmoplantar pustulosis remains an area of debate. Several authors propose that PPP is a distinct entity, while others believe PPP is a variant of psoriasis.

Epidemiology/presentation

Palmoplantar pustular psoriasis (PPP) presents clinically as sterile pustules with erythema, hyperkeratosis, and scaling on the palms and soles (Figure 2). The disease tends to predominate on the thenar, hypothenar, and central areas of the palms, as well as the corresponding areas of the soles, and it can extend proximally to the patient’s wrists and heels. The pustular lesions may expand and coalesce before resolving, commonly resulting in a brown discoloration upon resolution. PPP affects female more frequently than male. A study conducted in Japan comparing the clinical and epidemiological characteristics of PPP and palmoplantar psoriasis found a significant female predominance of 67%.

Pathophysiology

Multiple precipitating factors have been found to predispose patients to the induction of palmoplantar psoriasis, including smoking, metal sensitivities, infections, trauma, stress, and medications.

Effective as adjunctive therapy with systemic retinoids for maintenance (but contraindicated in children <12 years old)
can be found in the acrosyringium. Patients with PPP are thought to have an abnormal response to nicotine, resulting in inflammation with smoking. The role of smoking in the pathogenesis of PPP is further supported by the findings that cessation of smoking can lead to improvement or near resolution of PPP.

Sensitivities to metals have also been cited as precipitating factors in PPP. The most common metal sensitivity described is to nickel and occurs in 3% of patients with PPP. Other metal allergies described include chrome and cobalt.

Infections are another well-recognized precipitating factor for PPP. The most commonly cited infection resulting in an eruption or exacerbation of PPP is tonsillitis. According to Takahara, tonsillectomy in patients resulted in subjective improvement of the disease in 94% and objective improvement of the disease in 88% of patients with PPP. Other infections associated with PPP include dental infections such as dental alveolar abscesses, periodontitis, and dental caries, as well as sinusitis. The theory that focal infections play a central role in the exacerbation of PPP is supported by evidence of improvement or near resolution of skin findings following resolution of the patient’s infection.

The Koebner phenomenon can also be associated with new lesions in PPP. In PPP, mechanical stimulation is commonly caused by shoes, resulting in lesions on the soles of patients predisposed to the development of PPP.

Stressful psychological conditions also impact the onset and worsening of PPP. Results from questionnaires provided to patients with PPP showed that 43% of patients with PPP exhibited behaviors consistent with anxiety, worry, and psychosomatic disorders, compared to only 19% of subjects in the control groups. Others have shown that up to 46% of patients report worsening of PPP during periods of stress.

Furthermore, a seasonal influence has also been described for the onset of PPP with the onset and exacerbation worsened by humid and hot conditions.

Perhaps the most frustrating precipitating factor noted for PPP is the association with anti-TNF-α inhibitors. The importance of TNF-α-inhibitory therapy as a mainstay for treatment in chronic plaque psoriasis is well known. However, treatment of psoriasis with TNF-α inhibitors can cause a paradoxical flare of pustular psoriasis, especially of the palmoplantar morphology. This effect has been noted to be a class effect with most TNF-α blocking medications, rather than with specific agents. The mechanism behind the relationship between PPP and TNF-α inhibitor therapy remains to be elucidated.

In support of the theory that PPP is a distinct entity from psoriasis vulgaris, authors have discussed the morphological, clinical, and histological similarities between PPP and psoriasis. Yamamoto discussed the relationship between PPP and psoriasis with evidence of the eruption of plaque-like lesions on the trunk of individuals diagnosed with PPP. Brunasso et al supported the same relationship with a retrospective study comparing two groups of patients, one with PPP and the other with psoriasis, and found close similarities between the groups in age of onset, family history of psoriasis, duration of the disease, comorbidities, and smoking status. Eriksson et al discussed similarities regarding the histology of the two diseases, specifically regarding neutrophil dysfunction and specific serum studies including eosinophilic cationic protein elevations and other chemokinetic effects in PPP compared to psoriasis vulgaris.

Authors in support of the theory that PPP is a distinct entity from psoriasis vulgaris argue several different points. Many authors discuss the strong genetic evidence of differences between PPP and psoriasis, specifically, the absence of association with PSORS1 locus in PPP, which is common for psoriasis vulgaris, and the presence of IL-36RA mutations in some patients with PPP, which are lacking in patients with psoriasis vulgaris. Other authors argue that the strong association between smoking and metal intolerance with PPP that is absent in psoriasis vulgaris warrants distinct classification of the disease. PPP is also associated with SAPHO syndrome (synovitis, acne, palmoplantar pustulosis, hyperostosis, and osteitis), a syndrome that does not have an association with psoriasis vulgaris.

The pathophysiology of PPP remains as obscure as its classification. It is widely accepted, however, that the eccrine sweat gland is significant to its pathogenesis. Specifically, the acrosyringium (the most intraepidermal portion of the eccrine sweat gland consisting of the terminal spiral duct) serves as the primary site of inflammation and pustule formation, as supported by evidence of specific chemicals unique to eccrine sweat glands found in the cells lining the vesicles of PPP patients. Furthermore, recent studies have begun to emphasize the importance of the innate immune system in the development of PPP. Langerhans cells can be found in increased numbers in both lesional and nonlesional skin of PPP patients, supporting an antigen-driven process for inflammation in the disease. The inflammation is further driven by the proliferation of inflammatory cytokines such as IL-8 and IL-17. IL-17A is highly expressed in the palms.
and soles of patients with PPP in comparison to healthy subjects, while interestingly, IL-12 and IL-23 are not significantly expressed in these areas of patients with PPP. These findings imply a more central role for IL-17A in the inflammatory process for PPP compared to IL-12/IL-23, a difference which could have important implications for treatment.

**Treatment**

Palmoplantar forms of psoriasis are notoriously recalcitrant to therapy. Uncertainties regarding the pathophysiology of palmoplantar disease lead to lack of a biogenetic understanding for the development of new pharmacological therapies. Like other pustular psoriasis forms, high-quality data regarding the treatment options and efficacies are lacking for PPP. First-line topical therapy involves corticosteroids under occlusion (Table 4). Adisen et al have described successful use of topical corticosteroids, especially under occlusive dressing, for the prevention of new pustule formation in PPP, as well. Second-line topical therapy includes calcipotriene, PUVA, photodynamic therapy, and tacrolimus. Topical treatment, however, uncommonly leads to remission of the disease, and progression to systemic treatment is often required. First-line systemic therapy for PPP includes acitretin.

Second-line systemic therapy involves the use of cyclosporine and biologic agents. The use of biologic agents in the treatment of PPP is becoming more pervasive, given the recalcitrant nature of the disease. The use of anti-TNF-α blocking agents, including adalimumab, etanercept, and infliximab, in PPP has been reported to be successful in case reports and small studies. Morales-Munera et al have described the successful use of ustekinumab in five patients with severe, refractory palmoplantar pustulosis, all of whom experienced positive results in 2–3 weeks after the first dose and complete resolution at 20 weeks after therapy. Cases of PPP successfully treated with efalizumab, an anti-leukocyte function-associated antigen-1 monoclonal antibody, have also been reported. However, efalizumab has since been removed from the market secondary to concerns regarding progressive multifocal leukoencephalopathy.

Acrodermatitis continua of Hallopeau

History

ACH is another localized form of pustular psoriasis which is historically described using a number of various aliases including acrodermatitis perstans, dermatitis repens, acropustulosis, and pustular acrodermatitis. The classification of ACH has also been controversial since it was first described, with some authors considering ACH a skin disorder distinct from GPP and others considering ACH to be a variant of the generalized pustular disease.

Epidemiology/presentation

ACH is a chronic form of pustular psoriasis that characteristically involves the digits and most commonly, the fingertips and nails. ACH often presents as sterile pustules on the most distal portions of the fingers and toes (Figure 3). It is often painful and extensive with characteristic proximal progression of the sterile pustules leading to onychodystrophy or anonychia. ACH can have a similar presentation to other pustular disorders of the hands and feet, especially palmoplantar pustulosis. Characteristics that can be utilized to distinguish the various etiologies include ACH’s predisposition for the periungual areas as well as its ability to remain localized to a limited number of digits for many years. ACH is most common in middle-aged females. Further epidemiologic studies have not been conducted owing to the rarity of disease, and as such, most data have been obtained from anecdotal reports.

Pathophysiology

ACH, like GPP, is also associated with precipitating factors. Those precipitating factors most closely associated with ACH include localized trauma to the distal portion of a digit and localized infections.

As mentioned, the classification of ACH has long been debated with ACH possibly being a distinct disease or a variant of GPP. Support for the latter classification is provided both by case reports involving the transition of ACH to GPP and the presence of IL-36RA mutations in patients with ACH, which is the same genetic mutation found in some patients with GPP.

Treatment

Treatment of ACH is primarily based on data from case reports. ACH is notoriously recalcitrant to many therapies. Treatments that have been attempted historically included antibiotics and tar. Current first-line topical treatment for ACH is corticosteroid use under occlusion (Table 5). Second-line topical treatments include calcipotriol, tacrolimus, and fluorouracil, or a combination of these medications. However, these medications often do not prevent the occurrence of relapses and progression to systemic treatment is often necessary. First-line systemic therapies involve the use of cyclosporine and acitretin, and biologic agents. Biologic agents have more recently become the mainstay of treatment in recalcitrant forms of ACH. Ustekinumab was successfully used to treat a patient with ACH. TNF-α inhibitors have proven to be the most efficacious and include the use of infliximab, adalimumab, and etanercept, especially in recalcitrant cases of ACH. Efalizumab has also historically been used successfully in the treatment of ACH, but efalizumab, as mentioned, is no longer commercially available. Second-line systemic therapies include systemic corticosteroids, methotrexate, retinoids, PUVA, and narrow- and broad-band UVB.

Evidence-based treatment strategies for ACH are lacking due to the difficulty in diagnosis of ACH and the lack of knowledge regarding the pathophysiology and etiology of the disease. Future management of ACH requires larger controlled studies and further studies on the pathophysiology of the disease, which will likely guide the development of new and effective medications for treatment.

Psoriasis: Targets and Therapy 2016:6

Conclusion
Psoriasis vulgaris is a chronic inflammatory disease that classically affects skin and joints and is associated with numerous comorbidities. There are several clinical subtypes of psoriasis including the uncommon pustular variants, which include acute GPP, pustular psoriasis of pregnancy, infantile and juvenile pustular psoriasis, ACH, and PPP. These variants have similar histopathologic characteristics. However, the immunopathogenesis of each entity remains to be fully elucidated. As such, numerous therapies have shown variable results and most entities remain difficult to treat. In general, topical therapy should be used with less severe, more localized forms of the disease. There should be a low threshold to initiate systemic therapies, as most pustular forms of psoriasis are recalcitrant to topical and multiple systemic therapies. Combinations of systemic and topical therapies are encouraged. With increasing knowledge of the pathogenesis of these variants of pustular psoriasis, the development and use of biologic and other immunomodulatory therapies holds promise for the future of successfully treating pustular variants of psoriasis – including the therapies targeting IL-1, IL-17, the p19 unit of IL-23, and potentially IL-36.

Acknowledgment
We would like to thank Professor Alan Menter for providing the clinical images for the figures presented and for his continued mentorship.
