Abstract: Nanoemulsions (NEs) are used as transdermal drug delivery systems for systematic therapeutic purposes. We hypothesized that the skin permeation profile of an NE could be modulated by incorporating it into a hydrogel containing differing proportions of thickening agent. The objectives of this study were as follows: 1) to determine the stability and skin irritability of NE gels (NGs) containing 1%, 2%, and 3% (w/w) Carbopol® 934 (CP934) (termed NG1, NG2, and NG3, respectively); 2) to compare the skin permeation profiles and drug deposition patterns of the NGs; and 3) to visualize the drug delivery routes of the NGs. Terbinafine and citral were incorporated into the NGs as model drugs. Ex vivo skin permeation tests indicated that the percutaneous flux rates of terbinafine decreased in the order NE (215 µg/cm²) > NG1 (213 µg/cm²) > NG2 (123 µg/cm²) > NG3 (74.3 µg/cm²). The flux rates of citral decreased in the order NE (1,026 µg/cm²) > NG1 (1,021 µg/cm²) > NG2 (541 µg/cm²) > NG3 (353 µg/cm²). The NGs accumulated greater amounts of the drugs in the stratum corneum and less in the epidermis/dermis than did the NE ($P < 0.05$) over a period of 12 h. Laser scanning confocal microscopy indicated that the NGs altered the main drug delivery routes from skin appendages to intercellular paths. Histological images suggested that perturbations to the skin structure, specifically the size of the epidermal intercellular spaces and the separation distance of dermal collagen bundles, could be significantly minimized by increasing the proportion of CP934. These results suggest that adjustments of the CP934 proportions can be used to modulate the skin permeation profiles of NGs for specific therapeutic purposes.

Keywords: nanoemulsion, nanoemulsion gel, Carbopol 934 proportion, topical drug delivery, transdermal drug delivery

Introduction

Topical application formulations are designed as either transdermal or topical drug delivery systems. Transdermal drug delivery systems aim to transport drugs across skin layers so that the drugs can be taken up by the systemic circulation system. In comparison, topical drug delivery systems are intended for localized therapeutic action on one or more layers of skin.^{1,2} Recently, nanotechnology has been utilized to make novel drug carriers with potent skin permeation profiles and high drug-loading capacity for both transdermal and topical drug delivery systems. The nanocarriers include liposomes, ethosomes, polymeric nanoparticles, and nanoemulsions (NEs).³ Among these, NEs have been studied most extensively.

NEs are a broad class of multiphase colloidal dispersions with droplet size <100 nm. Consisting of a surfactant, cosurfactant, water, and oil, NEs have many characteristics that make them attractive to the pharmaceutical industry as possible drug nanocarriers.

These characteristics include easy preparation, promising drug-loading capacity, potent transdermal efficiency, and good controlled-release capacity.⁴ NEs were initially designed as transdermal drug delivery systems for systemic therapeutic purposes (eg, candidiasis and breast cancer). This is because NEs can penetrate all skin layers to reach the systemic circulation system, thereby avoiding hepatic toxicity and cumbersome administration procedures.⁵ NEs have also been recommended for topical therapeutic aims (eg, acne and psoriasis). However, this may result in drugs being unduly absorbed by the circulation system, thus reducing drug efficacy in certain targeted sites and inducing unwanted irritation and hemolysis.^{6–8} In addition, topical application of NEs is inconvenient due to their low viscosity. If their viscosity were increased, the skin permeation profiles of NEs could be modulated for either transdermal or topical drug delivery. This would expand the clinical application of NEs.

Hydrogels are three-dimensional polymeric networks that are capable of absorbing large amounts of water or biological fluids.⁹ The pharmaceutical industry has great interest in hydrogels because of their adhesiveness, semi-solid consistency, swelling behavior, and biocompatibility.¹⁰ Hydrogels have a mesh-like matrix structure, with openings typically between 5 and 100 nm wide.¹¹ The cross-linking density of the matrix can be augmented by increasing the amount of thickening agent in hydrogels.¹² This could be useful for modifying drug release kinetics and skin permeation profiles.^{13,14} It has been suggested that the viscosity of an NE could be optimized and its skin permeation profile modified by adjusting the proportion of thickening agent in a gel matrix containing an NE.

In this study, a series of NE gels (NGs) were produced by incorporating an NE into gel matrixes containing different proportions of Carbopol® 934 (CP934). The objectives of the study were as follows: 1) to determine the stability and skin irritability of the NGs; 2) to compare the skin permeation profiles and drug deposition patterns of the NGs; and 3) to visualize the drug delivery routes of the NGs. Terbinafine (TER) and citral (CIT) were used as model drugs in this study.

Materials and methods

Chemical compounds

CIT and TER were obtained from the Shanghai Ziyi Reagent Co, Ltd (Shanghai, China) and the Hubei Hengshuo Chemical Co, Ltd (Wuhan, China), respectively. Standard CIT (98% purity) was purchased from Dr Ehrenstorfer GmbH (Augsburg, Germany). Standard TER (99% purity) was purchased from the National Institutes for Food and Drug Control

(Beijing, China). CP934, Cremophor® EL (EL-40 and EL-35), Polysorbate 80 (Tw-80) and Cremophor RH-40 were purchased from the Tianjin Kemiou Chemical Reagent Co, Ltd (Tianjin, China). Ethanol, 1,2-propylene glycol, n-butyl alcohol, and glycerin were purchased from the Sichuan Xilong Chemical Co, Ltd (Chengdu, China). 2,5-Bis(5-tert-butyl-2-benzoxazolyl)thiophene (BBOT, 95% purity) was purchased from the Tokyo Chemical Industry Co, Ltd (Tokyo, Japan).

Animals

Guinea pigs (2 months old, 300–500 g weight; 30 males and 30 females) were obtained from the Laboratory Animal Center, College of Medicine, Xi'an Jiaotong University (Xi'an, China). The guinea pigs were housed in clear cages with standard food and water. All procedures in this study were in accordance with the Institutional Guidelines for Animal Experiments in Shaanxi Province, People's Republic of China. The procedures were approved by the Institutional Animal Care and Use Committee of Northwest A&F University (Yangling, China).

Preparation of NE and NGs

The surfactants were screened according to the methods of Azeem et al.¹⁵ Briefly, each surfactant (Cremophor EL-40, Cremophor EL-35, Tw-80, and Cremophor RH-40) was mixed with deionized water at a 15% (w/w) concentration. A 4 μ L aliquot of CIT was added to the solution, and then the solution was vortexed for 5 min. This procedure was repeated until the solution became turbid. The solution that dissolved the largest amount of CIT was selected as the best surfactant.

The best cosurfactant and the best surfactant–cosurfactant (K_m) ratio were determined by constructing pseudoternary diagrams using the water titration method.¹⁵ Briefly, the best surfactant was mixed with one of four cosurfactants (ie, ethanol, 1,2-propylene glycol, n-butyl alcohol, or glycerin) at a 3:1 (w/w) ratio to form four surfactant–cosurfactant mixes (S_{mix}). Then, CIT was blended with each S_{mix} at ratios of 1:9, 1:8, 1:7, 1:6, 1:5, 1:4, 1:3, 1:2, and 1:1 (w/w). The best cosurfactant was the S_{mix} with the largest NE phase (ie, clear, transparent, and viscous liquid phase). The best K_m ratio was determined by mixing the best surfactant with the best cosurfactant at ratios of 1:0, 1:1, 2:1, 3:1, 4:1, and 5:1 (w/w). The optimum K_m ratio was the one with the largest area in the pseudoternary diagram. The optimized NE was then prepared by mixing TER and CIT into the best S_{mix} using a water titration method.

The NGs were prepared by mixing NE into gel bases containing CP934, as described by Hussain et al⁷ with slight modifications. First, the gel bases were prepared by dispersing different amounts of CP934 in deionized water and then stirring (120 rpm) with a magnetic stirring bead for 3 h at room temperature. The gel bases contained 1%, 2%, or 3% CP934 (w/v). Second, triethanolamine was added to the gel bases. The mixtures were stirred at 60 rpm, and the pH was adjusted to 7.0. The gel bases were allowed to stand overnight to allow trapped air to escape and to allow cross-linking between CP934 and triethanolamine. Finally, the gel bases were separately mixed with NE at a 1:1 (w/w) ratio and stirred (120 rpm) at room temperature until the NGs were homogeneous and clear. The NGs containing 1%, 2%, and 3% CP934 plus NE will be referred to hereafter as NG1, NG2, and NG3, respectively.

Characterization of NE and NGs

The pH of the NE and NGs was determined with a digital pH meter. The polydispersity index (PDI) and droplet size distribution (DSD) were analyzed by Mastersizer 2,000 laser diffractometer (Malvern Instruments, Malvern, UK). The zeta potential was tested with a Zetasizer Nano ZS (Malvern Instruments). The formulations were diluted 10-fold and then dried on carbon-coated copper grids at room temperature prior to observation with a Hitachi JEOL-1230 transmission electron microscope (Hitachi Hitachi-Technologies Corp, Tokyo, Japan) at 80 kV.

Stability tests

The effect of extreme gravitational force, temperature, and pH on the NE and NGs was determined immediately after their preparation. The effect of extreme gravitational force was tested by centrifugation at either 5,000 or 12,000 rpm for 30 min. Temperature stability was tested by heating samples in a water bath at either 65°C or 95°C for 30 min, followed by cooling at room temperature. The pH effects were determined by adjusting the NE and NGs to pH 2, 3, 4, 5, 6, 8, or 9 with either 0.1 N HCl or 0.1 N NaOH. The samples were kept at room temperature for 24 h after these extreme treatments and then observed for separation, creaming, and cracking. Stable samples were assessed for DSD, PDI, and zeta potential, as described earlier. Untreated NE was used as a negative control.

Draize skin irritation test

Skin irritation tests were conducted as described by Draize et al.¹⁶ An electric razor was used to clip the hair from two

areas (2 cm diameter) in the middorsal region of 36 guinea pigs. Then, one of the two areas on each guinea pig was kept intact, while the other was rubbed with abrasive paper. The guinea pigs were then randomly divided into six groups (three females and three males for each group). After 24 h, 500 µL NE, 0.5 g NG (ie, NG1, NG2, or NG3), 500 µL blank NE (BNE; S_{mix} without Carbopol), 0.5 g CP934 gel (gel base), 500 µL phosphate-buffered saline (PBS) (negative control), or 500 µL formalin solution (1%, v/v, positive control) was spread thoroughly over a vaseline-ringed zone (1.5 cm diameter) of intact or abraded skin for each guinea pig in specific groups. The areas were then covered with gauze and an adhesive plaster. The areas were observed after 24, 48, and 72 h. Visible changes on the skin were observed and marked according to the mean values of erythema (no erythema, 0; light pink, 1; dark pink, 2; light red, 3; and dark red, 4) and edema (no edema, 0; barely perceptible, 1; edges definitely raised, 2; raised up to 1 mm with distinct outline, 3; raised >1 mm and expanded beyond the area of exposure, 4). Mean values of 0–0.49 indicated no irritation, 0.5–2.99 indicated light irritation, 3.0–5.99 indicated moderate irritation, and 6–8 indicated severe irritation.

Determination of TER and CIT

A Hitachi L-2000 series liquid chromatography system (Hitachi, Tokyo, Japan) was used to analyze the TER and CIT in the NE and NGs. The analytical column was a reversed-phase column (C18, 4.6 mm × 25 cm, 5 µm pore size) (Welch Materials Inc, Ellicott City, MD, USA). The NE and NGs were initially diluted 10-fold with methanol and then sonicated to degas. The supernatants were filtered through a 0.45 µm membrane filter for high-performance liquid chromatography (HPLC) analysis at 324 nm. The mobile phase was composed of methanol and deionized water (v/v, 8:2); the pH was 3.24; and the flow rate was 1.1 mL/min. Linear calibration curves were prepared in the range of 0.459–117.5 µg/mL for TER and 0.5176–132.5 µg/mL for CIT. The quantitative HPLC method was validated in terms of linearity, precision, accuracy, and percent recovery.

Ex vivo skin permeability tests

Ex vivo skin permeability tests were performed using Franz diffusion cells with guinea pig abdominal skin as the transdermal membrane (5 mL receptor volume, 0.785 cm² diffusion area).¹⁷ An electric razor was used to clip the hair from the abdomen of the guinea pigs. The clipped areas were examined the next day, and guinea pigs with intact skin were chosen for the tests. The guinea pigs were

ethically narcotized with diethyl ether, and a circular patch of abdominal skin (1.5 cm diameter) was excised using a corneal trephine. The wounds were then sterilized and sutured. The abdominal skin was put between the receiver chamber, which contained 5 mL PBS, and the donor chamber. The stratum corneum (SC) faced the donor chamber. A magnetic bead stirred the PBS in the receptor chamber (300 rpm). The temperature in the diffusion cells was maintained at $37^{\circ}\text{C}\pm 1^{\circ}\text{C}$. The donor chambers were filled with NE, one of the NGs, or conventional gel (CG, gel base with 1.5% CP934) containing TER and CIT. The amounts of TER and CIT were equivalent to that of 2 mL NE. A 2 mL aliquot of PBS was withdrawn from the receptor chamber after 0.5, 1, 2, 3, 4, 6, 8, 12, 16, and 24 h and replenished with another 2 mL PBS. The concentrations of TER and CIT in the PBS solutions were analyzed by HPLC. The cumulative amounts of the drugs per unit area in the receiver chamber (Q_n , $\mu\text{g}/\text{cm}^2$) were plotted as a function of time (h). The steady state flux (J_{ss} , $\mu\text{g}/\text{cm}^2/\text{h}$, permeation rate) was calculated from the slope of the linear portion (0.5–24 h) of the line. The enhancement ratio was calculated by dividing the J_{ss} values of the NE and NGs by the J_{ss} value of CG. All tests were conducted in triplicate.

TER and CIT in the SC and epidermis/dermis

The amounts of TER and CIT in the SC and epidermis/dermis were measured at three time intervals (ie, 2, 6, and 12 h) during the ex vivo skin permeability tests.¹⁸ The skins were collected and washed with warm PBS. The SC was removed using adhesive tape and then extracted with 4 mL methanol at 20°C for 1 h. The solutions were vortexed four times, each for 30 s, during the extraction. The epidermis/dermis was cut into small pieces and then extracted in the same way as the SC. The methanol solutions were centrifuged at 3,000 rpm for 10 min, and the supernatants were analyzed by HPLC.

Visualization of drug diffusion into skin

The NE, NGs, and CG containing BBOT were prepared as follows. First, 0.05 g BBOT was dissolved in 1.25 g TER-and-CIT mixture (w/w, 1:4) as the oil phase. Then, the NE, NGs, and CG (control) were prepared as previously described. The abdominal hair on 10 male guinea pigs was shaved before the test. Vaseline was used to make a border on the exposed abdominal skin. Subsequently, 200 μL NE, 0.625 g NG (ie, NG1, NG2, or NG3), or 0.625 g CG were separately applied to the skin of the guinea pigs. Each

formulation was applied to three guinea pigs. The marginalized skin areas were then covered with chambers. One guinea pig from each treatment was randomly selected at 2, 6, and 12 h. The abdominal skin was excised as described earlier in the skin permeability tests. The skins were washed with warm PBS and then stored at -80°C . Frozen skin sections (6 μm thick) were visualized using laser scanning confocal microscopy (CLSM) at the excitation wavelength of 405 nm. In order to determine whether BBOT dissolved in media other than CIT, 0.05 g BBOT was dissolved in S_{mix} (NE without TER and CIT, Blank NE, and BNE) and then visualized using CLSM.

Histological investigation of full-thickness abdominal skin

Exposed guinea pig abdominal skins were treated with the NE and NGs. After 2, 6, and 12 h, the treated guinea pigs were narcotized, and skin samples were taken as described for the ex vivo skin permeability tests. Skin samples were also collected from one guinea pig without treatment as a control. The skin samples were stored in 10% formalin solutions for 12 h. Later, the fixed samples were dehydrated with ethanol and fixed in paraffin. The paraffin sections were stained with hematoxylin and eosin and then observed under an Olympus light microscope.

Statistical analysis

The data were expressed as mean $\pm$ standard deviation, but the enhanced ratio values and Draize test values were in their original form. For comparison of the values among groups, one-way analysis of variance was used. To determine the statistical significance, the Tukey–Kramer multiple comparison test was used. When the P -value was less than 0.05 and 0.01, the difference between values was considered statistically significant or of higher significance, respectively.

Results and discussion

Preparation of NE and NG

The solubility of CIT was greater in EL-40 (56 μL) than in EL-35 (44 μL), TW-80 (52 μL), and RH-40 (52 μL) (data not shown). In the cosurfactant tests, 1,2-propylene glycol (Figure 1A) had the largest NE field, followed by ethanol, glycerin, and then n-butyl alcohol (Figure 1B–D). This indicated that 1,2-propylene glycol penetrated the interfacial film, thus increasing interfacial fluidity by permitting the hydrolytic tails of EL-40 to move freely.¹⁹ Therefore, 1,2-propylene glycol was selected as the best cosurfactant.

Figure 1 Pseudoternary phase diagrams of four cosurfactants combined with EL-40 at fixed mass ratio (1:1).

Notes: (A) 1,2-Propylene glycol; (B) glycerin; (C) ethanol; and (D) n-butyl alcohol.
Abbreviations: EL-40, Cremophor EL-40; Smix, mix of surfactant and cosurfactant.

Pseudoternary phase diagrams were prepared using various ratios of EL-40 and 1,2-propylene glycol. The 3:1 K_m value exhibited the largest area and was therefore selected as the optimum K_m ratio (Figure 2A–F). The optimum S_{mix} (ie, 3:1 ratio of EL-40 and 1,2-propanediol), TER, CIT, and water were combined at a ratio 24:1:4:71 (w/w) to produce the optimized NE. The NE was then mixed with gel base containing different proportions of CP934 to produce NG1, NG2, and NG3.

The pH of the NE and NGs was neutral (6.9 ± 0.2). Therefore, they were suitable for application on skin and unlikely to induce irritation. The DSD of the NE and NGs was determined immediately after their production (Figure 3A–D). The DSDs were in the nanoscale for NE, NG1, NG2, and NG3, averaging 15.53 ± 3.32 , 14.88 ± 3.11 , 17.16 ± 5.45 , and 15.79 ± 5.42 nm, respectively. The PDIs for NE, NG1, NG2,

and NG3 were 0.074 ± 0.009 , 0.084 ± 0.025 , 0.092 ± 0.014 , and 0.075 ± 0.008 , respectively. The zeta potentials for NE, NG1, NG2, and NG3 were -7.4 ± 1.8 , -6.5 ± 2.3 , -6.16 ± 2.1 , and -5.3 ± 1.7 mV, respectively (Figure 4A–D). The transmission electron microscopy images showed that the NE and NG droplets were spherical (Figure 5A–D). The droplets did not aggregate after incorporation into CP934 gel, which was consistent with previous reports.^{7,20}

Stability test

Centrifugation, temperature, and pH greatly influence the physical stability of NEs, affecting the DSD, PDI, and zeta potential.²¹ Centrifugation had no significant effect on these variables in either the NE or the NGs ($P > 0.05$, Table 1). This meant that the NGs were kinetically stable against gravitational separation.

Figure 2 Pseudoternary phase diagrams of various K_m ratios of EL-40 and 1,2-propylene glycol.

Notes: (A) K_m : 1:0; (B) K_m : 1:2; (C) K_m : 1:3; (D) K_m : 2:1; (E) K_m : 3:1; and (F) K_m : 4:1.

Abbreviations: EL-40, Cremophor EL-40; K_m , surfactant-cosurfactant; Smix, mix of surfactant and cosurfactant.

Heating significantly reduced the stability of the NE and NGs (Table 1). The average droplet size of NG2 and NG3 was highly significantly smaller than that of NE and NG1 in the 65°C treatment ($P < 0.01$). Similar differences were observed in the PDIs ($P < 0.05$) but not in the zeta potential values

($P > 0.05$). One explanation is that high temperatures increase droplet movements, causing the droplets to coalesce. High temperatures could also cause reorientation of the emulsifier's crystalline structure. A reduction in OH^- on the film surface would cause the absolute zeta potential to decrease.^{22,23}

Figure 3 Droplet size distribution immediately after production.

Notes: (A) NE; (B) NG1; (C) NG2; and (D) NG3. NG1, NG2, NG3: NE gels containing 1%, 2%, and 3% (w/w) Carbopol® 934, respectively.

Abbreviations: d, diameter; NE, nanoemulsion; NG, NE gel.

However, it is important to mention that the droplet size and the PDI of the NGs remained small as the CP934 proportion increased. This indicated that especially in large proportions, the CP934 gel matrix increases the thermodynamic stability of NE. This may be because the mesh size of the NG network decreases as the proportion of CP934 increases. The narrow mesh size could confine droplet movement. In the 95°C treatment, NE became opaque, cloudy, and then the drugs separated out (Table 1, data not shown). This implied that the film covering the oil droplets ruptured upon reaching the cloud point of EL-40, causing EL-40 to separate from the solution due to the breaking of hydrogen bonds between polyoxyethylene and water. The cloud point range of EL-40 is 70°C–84°C. The manufacturer reported a cloud point of 80°C. Although their stability was significantly reduced by heat ($P < 0.05$), the NGs were less affected than the NE. Overall, the results indicated that the gel matrix increased the thermodynamic stability.

Extreme pH, (ie, pH 2, 3, and 9) significantly affected the zeta potential and droplet size of both the NE and the NGs ($P < 0.05$, Figure 6A and B). In contrast, the pH had no significant effect on PDI (data not shown). Hydroxyl ions (OH^-) adhering to the oil/EL-40/water film result in negative zeta potential. The OH^- can be replaced by hydrogen ions (H^+) from the medium, exhibiting less negative zeta potential initially and then even neutral or positive zeta potential as the H^+ replaces more OH^- moieties.^{24,25} Therefore, the low pH reduced the absolute zeta potential, thus inducing droplet aggregation. High pH had the opposite effect. The zeta potential of both the NE and the NGs decreased significantly at pH 4 ($P < 0.05$); however, droplet size remained stable ($P > 0.05$). It may be that a steric barrier was formed by the

hydration of the polyoxyethylene chains of EL-40.^{26,27} At pH 1, 2, and 3, the droplet size of NG3 was significantly smaller than that of NG2 and NG1 ($P < 0.05$). This meant that higher CP934 proportions make NGs more stable against extreme pH values.

Skin irritation test

Skin irritation potentials decreased in the order NE > NG1 > NG2 > NG3 (Table 2). The NE and NG1 treatments both demonstrated moderate-to-severe irritation in intact and abraded skin 48 and 72 h posttreatment. The NG2 treatment exhibited slight irritation. The NG3 treatment caused slight irritation to abraded skin but no irritation to intact skin. No irritation was observed in the gel base and BNE treatments during the test. This indicated that CP934, EL-40, and 1,2-propylene glycol are safe for topical use.^{15,28}

The SC is a formidable barrier that inhibits substances from penetrating into the deep skin layers where immune reactions can be triggered, especially the release of histamine by mast cells during inflammation or allergy.^{29,30} Barbier and Benezra³¹ reported that guinea pigs are sensitive to CIT, exhibiting delayed skin hypersensitivity after 24 h exposure at 0.5% (v/v, 0.5 mL). The results of this study showed that irritation was greater when the skin was abraded rather than intact. This meant that more CIT diffuses into the deep skin layers when the SC is removed. Furthermore, the skin irritation potential decreased as CP934 proportions increased. The NG3 treatment caused only moderate irritation to abraded skin and was deemed a safe topical formulation. The likely explanation is that smaller gel mesh in NG3 reduced droplet movement from the gel matrix to the deep skin layers. However, this mechanism needs

additional study using drug diffusion tests. Overall, the skin irritation potential of NGs can be reduced by increasing the CP934 proportion.

HPLC method for determination of TER and CIT in the NE and NGs

The HPLC results showed no interference among TER, CIT, and other excipients in the NE or NGs (Figure 7A and B). The TER and CIT used to prepare the NE and NGs had higher purity than standard TER and CIT (Figure 7C and D).

Interestingly, the retention time of TER was significantly influenced by the pH value of the mobile phase, showing a 5 min lag for every increase of 0.1 pH units. This is because additional H^+ ions in the medium are prone to protonate the pair of N atoms in TER, thus increasing its polarity and shortening the retention time.³² There were good linear relationships between the drug concentrations and their peak areas in the range of 0.459–117.5 $\mu\text{g/mL}$ for TER ($y=2\times 10^{-7}x-0.0385$, $r^2=0.9998$) and 0.5176–132.5 $\mu\text{g/mL}$ for CIT ($y=3\times 10^{-7}x-0.0122$, $r^2=0.9992$). The method showed

acceptable precision for TER and CIT analysis, with standard deviations less than 2% for both the intraday and interday assays. Furthermore, the mean recovery percentages were 99.85%±0.18% for TER and 99.71%±0.53% for CIT.

Ex vivo skin permeation test

The five formulations exhibited highly significant differences in cumulative drug permeation after 24 h (Table 3,

Figure 8A and B). Skin permeation decreased in the same order for both TER and CIT. Specifically, skin permeation by TER decreased in the order NE (215 µg/cm²) > NG1 (213 µg/cm²) > NG2 (123 µg/cm²) > NG3 (74.3 µg/cm²) > CG (41.6 µg/cm²). Skin permeation by CIT decreased in the order NE (1,026 µg/cm²) > NG1 (1,021 µg/cm²) > NG2 (541 µg/cm²) > NG3 (353 µg/cm²) > CG (175 µg/cm²). The Jss values of these five formulations (Table 3) coincide with

the results in Figure 8. The Jss values of TER for NE, NG1, NG2, and NG3 were 7.64-, 7.77-, 5.03-, and 3.01-fold higher, respectively, than for CG. The Jss values of CIT in NE, NG1, NG2, and NG3 were 5.19-, 5.21-, 3.03-, and 1.95-fold higher, respectively, than in CG. These results suggest that nanocarriers can play an important role in enhancing the permeability of drugs through the skin. The Jss values of NG2 and NG3 were significantly less than those of NE and NG1 ($P < 0.01$). This suggests that the smaller mesh size of the gel matrix in NG2 and NG3 hinders drug release and thereby reduces drug absorption by the systemic circulation in vivo. Further, a reduction in the drug diffusion rate means that an effective concentration of the drug could be maintained at the local skin layers for localized therapeutic purposes. This skin

permeation rate was greater in NG3 than in CG. Similar studies also reported that droplets moved more slowly from the inner phase to the outer phase in CG than in NG, probably because the droplets were larger in CG.^{33,34}

TER and CIT accumulation in the SC and epidermis/dermis

The SC and epidermis/dermis were collected 2, 6, and 12 h after topical administration of the NE or NGs to quantify the temporal changes in TER and CIT accumulation in the skin layers. The amounts of TER and CIT in the SC were significantly ($P < 0.05$) or highly significantly ($P < 0.01$) greater in the NGs and CG than in NE (Table 4). This suggested

that a relatively large amount of drug was deposited on the SC, probably due to the high affinity between CP934 and the SC.³⁵ The TER and CIT amounts decreased in the order NG1 > NG2 > NG3. One explanation is that the drug release rates decreased as the proportion of CP934 increased.³⁶ There were significant temporal reductions in drug deposition on the SC in both NG2 and NG3 treatments. This possibly occurred when drugs diffused out from the epidermis to the dermis, because it is well known that the dermis is less resistant than the epidermis to drug penetration.³⁷ In the deep skin layers (epidermis/dermis), drug deposition was highly significantly greater in NE and NG1 than in NG2 and NG3 ($P < 0.01$). Similarly, Welin-Berger et al³⁸ reported that the drug release rates decreased as the formulations increased in viscosity. The results of this study suggest that NE and NG1 contained more nanosized droplets than NG2 and NG3 to react with the SC within a short time span. Furthermore, the surfactants and cosurfactants in the NGs impair the barrier function of the SC.^{39,40} Therefore, NE and NG1 deposited more drugs than NE2 and NE3 in the dermis. In comparison, TER and CIT in CG barely permeated the SC into the deeper skin layers. This further supports the idea that the mesh structure of the gel matrix hindered large droplets from diffusing into the SC. The ability to deposit drugs on the SC demonstrates that topically applied NGs have potential for prolonged drug release. However, to meet specific treatment purposes, it is still necessary to know whether the drugs primarily accumulate in the epidermis or in the dermis.

Visualization of drug diffusion into the skin in vivo

CLSM based on the fluorophore fluorescein has become the conventional method for observing drug localization and permeation pathways in skin.^{7,41} The marker in this test was BBOT dissolved in CIT. The results were validated by the observation that no fluorescent signals were detected when BBOT was dissolved in BNE. The deposition of fluorescent CIT and TER in the skin layers increased as the treatment time with NE, NGs, and CG increased. Fluorescence intensity was generally stronger in NE and NG1 than in NG2 and NG3 throughout the test (Figure 9A–L). The intensity decreased in the order NE > NG1 > NG2 > NG3 > CG (Figure 9A–O). Drug delivery was generally confined to the outermost skin layers in CG (Figure 9M–O). In contrast, stronger fluorescence signals were observed in deeper skin layers in the treatments with NGs (Figure 9D–L). This clearly indicated that droplet size and NE excipients have great effect on skin permeability.

The findings agree with previous reports that NGs can significantly enhance skin permeability when compared with CGs, probably because NGs have smaller droplets.^{33,34} Moreover, differences in fluorescence signals among the NGs showed that the proportion of CP934 influenced the skin permeation rates by altering the main skin permeation routes. There are three major routes for drug penetration into the subepidermal tissue: hair follicles together with their sebaceous glands, sweat ducts, and the SC (including transcellular and intercellular routes).⁴² The images show that the penetration depths of NG1 (approximately 190 and 310 μm at 2 and 6 h, respectively; Figure 9D and E) and NG2 (approximately 110 and 210 μm at 2 and 6 h,

respectively; Figure 9G and H) were greater than those of NG3 (approximately 110 and 180 μm at 2 and 6 h, respectively; Figure 9J and K). In addition, it was obvious that NG1 and NG2 delivered the drugs more efficiently into follicles, sebaceous glands, and sweat ducts under the skin, making them “reservoirs” for delivering model drugs to deep skin layers. The model drugs in NG3 diffused uniformly in both the horizontal and vertical directions, resulting in drug deposition in the epidermis (Figure 9J–L). The reduced mobility of droplets in NG3 maybe because the high proportion of thickening agent reduced the mesh size of the gel matrix, thus hindering droplet movement to the surrounding pores and eventually leading to low skin permeation rate. This means that NG3 is superior to NG2 and NG1 for topical therapeutic effect.⁴³ These results agree with previous studies on NEs, which suggested that 1) hair follicles and sweat glands play an important role in transdermal drug delivery systems^{41,44} and 2) gel matrixes can increase drug retention time in the epidermis.⁴⁵ Comparison with NE indicated that as the proportion of CP934 increased in the NGs, the main skin delivery routes were altered and the skin permeation profiles were changed from the transdermal mode to topical drug delivery.

Histological investigation of skin treated with NE or NGs

Skin cross sections were prepared and observed microscopically to further elucidate the main delivery routes after topical application of NGs. The images of the negative control showed well-defined and adjacent margins between the SC, epidermis, and dermis (Figure 10A). The SC was intact. No inflamed cells were seen in the dermis. The skin appendages were normal, and the bundles of collagenous fibers were

tightly arranged. In comparison, the SC in the NE and the NG treatments exhibited clear morphological changes after 2, 6, and 12 h (Figure 10B–M). In NE (Figure 10B–D) and NG1 (Figure 10E–G), the SC was loosened into several distinct

and randomly twisted layers. The space among the layers increased as the treatment time increased, and fractures also formed. Similar changes were observed in the SC of NG2 (Figure 10H–J) and NG3 (Figure 10K–M); however, the SC

layers were more compact and there were fewer fractures than in NE and NG1. Surfactants and cosurfactants are both reported to extract intercellular lipids and break connections among keratinocyte desmosomes.^{39,40} Moreover, changes in the SC could be attributed to the movement of aqueous fluid into the polar pathway, thus increasing the interlamellar volume of the lipid bilayer in the SC.⁴⁶ However, it is important to note that changes to the SC were minimized as the proportion of CP934 increased. This indicated that fewer droplets came out from NGs containing high proportions of CP934. The NG2 and NG3 treatments only slightly perturbed the SC. In the NG3 treatment (Figure 10K–M), the SC remained intact at the end of the test.

In the epidermis, the NE and NGs resulted in enlarged intercellular spaces and distinct voids. The dermis exhibited abnormal separation of the collagenous bundles. The spaces in the epidermis and the separation of the collagenous bundles in the dermis became more prominent as treatment time increased. These results were similar with the findings of others,^{41,44,47,48} who observed that 1) NEs were mainly distributed in the extracellular space and 2) interlocking channels formed by proteoglycans in the interstices among the collagenous bundles can be enlarged to allow for the passage of substances. Zhao and Singh⁴⁹ reported that CIT can perturb the macroscopic structure of the skin barrier and extract the intercellular lipids. This could explain the histological changes in this study. As the proportion of CP934 in the NGs increased, the size of the intercellular spaces and the separation distance of the collagenous bundles decreased sharply and then leveled out. This indicated that within short periods of time, there was less drug diffusion from formulations with higher CP934 proportions (ie, NG2 and NG3). Thus, the images show that less space was needed for the passage of drugs and there were fewer changes to the dermis. Moreover, the results indicated that in NG2 and NG3, more drug was retained in the dermis rather than passing through. These results agree with both the ex vivo skin permeability tests and the visualization of drug diffusion in the skin. The histological images indicated no inflamed cells in the dermis in any treatment, suggesting that the NE and NGs are topically safe. These results agreed with the results of the skin irritation, ex vivo skin permeation, drug deposition tests, and CLSM images.

Conclusion

We successfully integrated NEs into CP934 gel to produce NGs. Stability tests and Draize tests indicated that the NGs are more stable and also safer than NEs. As the proportion

of CP934 in the gel matrix increased, 1) the skin permeation rates declined, 2) drug deposition in the epidermis/dermis increased, 3) the drug diffusion routes changed from skin appendages to mainly intercellular paths, and 4) histological structures were significantly altered. Overall, the results support the idea that the proportion of CP934 in the gel matrix can successfully modulate the skin permeation profiles of NGs, changing them from transdermal to topical drug delivery systems. The incorporation of NEs into hydrogel shows great promise for specific therapeutic purposes (ie, topical or systemic administration).

Acknowledgments

We thank Professor Mingqi Yang (Northwest A&F University) for his advice on preparation of skin histological cross sections. We thank Yunzhou Li, Kai Liu, Lina Gao, Guohua Bu, and Dan Liu for their sincere help and advice on collecting data. We appreciate and thank Dr William J Gale (Shihezi University, Shihezi, Xinjiang, China) for polishing the language.

International Journal of Nanomedicine

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Submit your manuscript here: <http://www.dovepress.com/international-journal-of-nanomedicine-journal>

Dovepress

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.
