Objective: Previous reports have demonstrated significant brain activity changes in bilateral blindness, whereas brain activity changes in late monocular blindness (MB) at rest are not well studied. Our study aimed to investigate spontaneous brain activity in patients with late middle-aged MB using the amplitude of low-frequency fluctuation (ALFF) method and their relationship with clinical features.

Methods: A total of 32 patients with MB (25 males and 7 females) and 32 healthy control (HC) subjects (25 males and 7 females), similar in age, sex, and education, were recruited for the study. All subjects were performed with resting-state functional magnetic resonance imaging scanning. The ALFF method was applied to evaluate spontaneous brain activity. The relationships between the ALFF signal values in different brain regions and clinical features in MB patients were investigated using correlation analysis.

Results: Compared with HCs, the MB patients had marked lower ALFF values in the left cerebellum anterior lobe, right parahippocampal gyrus, right cuneus, left precentral gyrus, and left paracentral lobule, but higher ALFF values in the right middle frontal gyrus, left middle frontal gyrus, and left supramarginal gyrus. However, there was no linear correlation between the mean ALFF signal values in brain regions and clinical manifestations in MB patients.

Conclusion: There were abnormal spontaneous activities in many brain regions including vision and vision-related regions, which might indicate the neuropathologic mechanisms of vision loss in the MB patients. Meanwhile, these brain activity changes might be used as a useful clinical indicator for MB.

Keywords: ALFF, monocular blindness, resting state, spontaneous activity

Introduction
Blindness has become a global health problem. There were 32.4 million people suffering from blindness in 2010 globally. Blindness can be caused by several ocular diseases, such as glaucoma, cataract, and globe injury. Blindness not only causes difficulties in daily life but also results in serious psychological problems (such as anxiety, sadness, and depression) for blind patients. Meanwhile, blindness also imposes a heavy economic burden on society. Around $5.5 billion per year is spent on medical care and nursing of blind patients in the USA.

The visual system consists of the eye, optic nerve, lateral geniculate body, and visual cortex, which are involved in processing visual information. Functional magnetic resonance imaging (fMRI) has been used to evaluate the brain activities in blindness.
Blindness leads to abnormality of the visual pathway and visual cortex. Early blindness subjects showed thicker occipital cortex. Other studies reported that early blindness patients had stronger auditory and parietal networks and weaker vision-related occipital networks compared with sighted subjects. Moreover, the blindness subjects showed decreased voxel-based functional connectivity density in the primary visual cortex (V1) and the primary somatosensory. However, changes in spontaneous brain activity were less understood in late monocular blindness (MB).

Amplitude of low-frequency fluctuation (ALFF) is a useful resting-state fMRI analysis method to evaluate regional brain activity at rest. In our previous studies, the ALFF method was successfully used to assess neurological conditions in some eye diseases, such as optic neuritis, glaucoma, and comitant strabismus. ALFF is considered to be a reliable and sensitive measurement, which can be used to evaluate spontaneous neural activity accurately. There were no obvious differences in weight ($P=0.704$) and age ($P=0.973$) between the two groups. There were significant marked differences in best-corrected visual acuity (VA)-right ($P<0.001$), or best-corrected VA-left ($P<0.001$) between the MB patients and healthy controls (HCs) (Table 1). This study explores changes in brain activity in patients with late MB compared with sighted subjects and investigates its relationship with the clinical manifestations.

### Materials and methods

#### Subjects

A total of 32 patients with MB (25 males and 7 females) were recruited from the Ophthalmology Department of the First Affiliated Hospital of Nanchang University Hospital. The diagnostic criteria for MB were as follows: 1) late stage of MB (18 patients with ocular trauma and 14 patients with keratitis) and 2) normal contralateral eye without any ocular diseases (such as cataracts, glaucoma, optic neuritis, and retinal degeneration). The exclusion criteria were as follows: 1) bilateral congenital blindness, 2) bilateral late blindness, 3) a history of surgery in both eyes, 4) long-term medical treatment of blindness, and 5) psychiatric disorders (such as depression, bipolar disorder, and sleep disorder) and cerebral infarction diseases (such as cerebral hemorrhage, cerebral infarction, and cerebral vascular malformations).

Thirty-two HCs (25 males and 7 females) with similar age, sex, and education to subjects in the MB group were also recruited in this study. All HCs met the following criteria: 1) no ocular disease with uncorrected or corrected VA $>1.0$, 2) no psychiatric disorders (such as depression, bipolar disorder, and sleep disorder), and 3) able to be scanned with MRI (eg, no cardiac pacemaker or implanted metal devices). All research methods followed the Declaration of Helsinki and were approved by the Medical Ethics Committee of the First Affiliated Hospital of Nanchang University. Our study was approved by the Institutional Review Board of the First Affiliated Hospital of Nanchang University. All subjects participated voluntarily and were informed of the purposes, contents, and risks before signing an informed consent form.

#### Methods

##### MRI parameters

MRI scanning was performed on a 3-Tesla MR scanner (Trio; Siemens, Munich, Germany). The functional data were obtained with a spoiled gradient-recalled echo sequence with the following parameters: 176 images (repetition time $=1,900$ ms, echo time $=2.26$ ms, thickness $=1.0$ mm, gap $=0.5$ mm, acquisition matrix $=256 \times 256$, field of view $=250 \times 250$ mm, flip angle $=90^\circ$). We also obtained 240 functional images (repetition time $=2,000$ ms, echo time $=30$ ms, thickness $=4.0$ mm, gap $=1.2$ mm, acquisition matrix $=64 \times 64$, flip angle $=90^\circ$, field of view $=220 \times 220$ mm, 29 axial slices with gradient-recalled echo-planar imaging pulse sequence).

##### fMRI data analysis

Functional data were classified using MRicro software (Nottingham University, Nottingham, UK), and incomplete data were removed. The rest of the data was preprocessed by DPARSFA (Institute of Psychology, CAS., Beijing, People’s Republic of China) software, including digital imaging and communications in medicine form transformation, slice timing, head-motion correction, spatial normalization, and smoothing with a Gaussian kernel of $6 \times 6 \times 6$ mm$^3$ full width
at half maximum. The subjects who had more than 1.5 mm maximum shift in x, y, or z and 1.5° of angular motion were rejected. Friston six head-motion parameters were used to regress out head-motion effects based on recent work showing that higher-order models were more effective in removing head-motion effects. Linear regression was also applied to remove other sources of false variables, which contained the signal from ventricular regions of interest and from a region centered in the brain’s white matter. After head-motion correction, the functional images were spatially normalized to the Montreal Neurological Institute space using the standard echo-planar imaging template. The time series of the blood-oxygen level dependent signal was converted to the frequency domain using the fast Fourier transform. The square root of the power spectrum was then calculated and averaged across 0.01–0.08 Hz for each voxel. The averaged square root was defined as the ALFF at the given voxel. To reduce the global effects of variability across the participants, the ALFF of each voxel was divided by the global mean ALFF value for each participant.

Statistical analysis
Statistical analysis was performed with a general linear model analysis using the SPM8 toolkit (The MathWorks, Inc., Natick, MA, USA) to calculate the ALFF signal group differences in resting state between MB patients and HCs, after controlling for the effects of age. The significance level was set at \( P < 0.05 \), Gaussian random field theory corrected, minimum \( z > 2.3 \).

Brain-behavior correlation analysis
Brain areas with different ALFF findings between groups were classified as regions of interest with the resting-state fMRI data analysis toolkit software. Finally, the relationship between the mean ALFF value in each area in the MB group and behavioral performances was calculated using correlation analysis (\( P < 0.05 \) significant differences).

Clinical data analysis
The cumulative clinical measurements, including the duration of the onset of MB and best-corrected VA, were recorded and analyzed in the study with independent sample \( t \)-test (\( P < 0.05 \) significant differences).

Results
ALFF differences
Compared with HCs, MB patients showed lower ALFF values in the left cerebellum anterior lobe, right parahippocampal gyrus, right cuneus (most significant difference), and left precentral gyrus/paracentral lobule (Figure 1 [blue] and Table 2). In contrast, higher ALFF values in the MB group were observed in the right middle frontal gyrus (MFG), left MFG (most significant difference), and left supramarginal gyrus (SMG) (Figure 1 [red] and Table 2). The mean ALFF values between the two groups were shown in Figure 2. In the MB group, there was no significant correlation between the mean ALFF values in these regions and the clinical manifestations (\( P > 0.05 \)).

Receiver operating characteristic curve
We hypothesized that the ALFF differences between the two groups might be useful diagnostic markers. The mean ALFF values in different brain regions were analyzed using the receiver operating characteristic (ROC) curves. When the area under the curve (AUC) is 0.5–0.7 it indicates accuracy is low, if it is 0.7–0.9 accuracy is certain. The AUCs for ALFF values were as follows: left cerebellum anterior lobe (0.824), right parahippocampal gyrus (0.796), right cuneus (0.731), and left precentral gyrus/left paracentral lobule (0.784) (MBs > HCs) (Figure 3A); right MFG (0.791), left MFG (0.868), and left SMG (0.819) (MBs < HCs) (Figure 3B).

Discussion
Our study evaluates the effect of middle-aged late MB on resting-state brain activity using the ALFF technique. Compared with HCs, patients with MB had significantly lower ALFF values in the left cerebellum anterior lobe, right parahippocampal gyrus, right cuneus, left precentral gyrus, and left paracentral lobule, but higher ALFF values in the right MFG, left MFG, and left SMG.

Analysis of the decreased ALFF values in the MB
The cuneus is involved in receiving visual information from the retina and is located in the occipital lobe. In addition, the dysfunction of cuneus has been related to many diseases including trigeminal neuralgia\(^{17} \) and schizophrenia.\(^{18} \) A previous study reported significantly decreased functional connectivities in the occipital visual cortex in the early blind patients.\(^{19} \) However, in our study, we observed that late MB patients showed significantly decreased ALFF values in the right cuneus, indicating cuneus dysfunction. We speculated that the late MB might lead to the abnormalities of the cuneus.

The parahippocampal gyrus is located in the inferior temporo-occipital cortex, surrounding the hippocampus. The parahippocampal gyrus is involved in visual scenes,\(^{20} \)
cognition,\textsuperscript{21} and spatial control.\textsuperscript{22} The parahippocampal gyrus has been suggested to control the processing of object and scene information.\textsuperscript{23} A previous study showed the activation of the parahippocampal gyrus when a three-dimensional spatial structure was presented.\textsuperscript{24} In addition, the dysfunction of the parahippocampal gyrus occurs in many diseases such as Alzheimer’s disease\textsuperscript{25} and schizophrenia.\textsuperscript{26} A previous report had demonstrated that MB patients showed less activity in the right dorsal parahippocampal gyrus compared with HCs.\textsuperscript{27} Consistent with these findings, we also found that there were

**Figure 1** Spontaneous brain activity in the monocular blindness and healthy control groups. 

*Notes:* Significant brain activity differences were observed in the left cerebellum anterior lobe, right parahippocampal gyrus, right cuneus, left precenral gyrus, left paracentral lobule, right middle frontal gyrus, left middle frontal gyrus and left supramarginal gyrus. The red or yellow denotes higher ALFF values, and the blue areas indicate lower ALFF values, respectively ($P<0.01$ for multiple comparisons using Gaussian random field theory ($z>2.3, P<0.01$, cluster $>40$ voxels, AlphaSim corrected)).

Notes: A P-value <0.05 was significantly different for multiple comparisons using Gaussian random field theory (z>2.3, P<0.01, cluster >40 voxels, AlphaSim corrected). “–” indicates the cerebellum anterior lobe did not belong to any Brodmann areas.

significantly lower ALFF values in the right parahippocampal gyrus in the MB patients. These results suggested that the late stage MB might lead to the dysfunction of the parahippocampal gyrus.

The cerebellum is involved in the execution of motor control. In addition, the cerebellum also regulates cognition. The cerebellum has been shown to be involved in the execution of accurate eye movement. Moreover, dysfunction of the cerebellum has been shown in many diseases such as autism, schizophrenia, and ataxia. A pervious study showed that there is increased blood flow in early blindness. Another study reported that MB patients showed lower benzodiazepine receptor density in the cerebellum compared with HCs. In our study, we also found that MB patients had significantly lower ALFF values in the left cerebellum anterior lobe. Both MB and binocular blindness can lead to the dysfunction of the cerebellum. Thus, we speculated that MB might cause dysfunction of the cerebellum.

Analysis of the increased ALFF values in the MB

The MFG is one-third of the frontal lobe and is involved in the working memory and attention control. A previous study demonstrated that early blindness showed decreased functional

In summary, our results showed that there were abnormal spontaneous activities in many brain regions including vision and vision-related regions, which might indicate the neuropathologic mechanisms of vision loss in the MB patients. In addition, these brain activity changes might be used as a useful clinical indicator for MB.

Prospects and limitations
The ALFF is a useful method that can be used to evaluate the whole-brain activity in patients. In addition, as a method of resting-state fMRI, the ALFF can be performed to scan the subject in the resting state. However, there are several limitations in our study. First, the inclusion criteria for MB are not strict. We included left eye or right eye blindness, which might also affect the accuracy of the results. Second, MB patients recruited had different time course of the disease, which might also affect the accuracy of the results. Third, during the scanning process, some subjects had some physical movement, which might influence the scanning results. In future studies, we will comprehensively use various techniques for investigating the neuropathologic changes in MB patients.
