Electrical stimulation therapy to promote healing of chronic wounds: a review of reviews

Pamela E Houghton

School of Physical Therapy, Faculty of Health Sciences, Western University, London, ON, Canada

Purpose: The overall objective of this study is to identify and appraise all of the existing clinical research literature that has evaluated the effect of electrical stimulation therapy (EST) on wound healing outcomes in adults with various types of chronic wounds.

Methods: A systematic and comprehensive search of four electronic databases and gray literature was carried out, and references included in related review articles were checked. Prospective and controlled clinical trials, systematic reviews (SRs), and meta-analyses that assessed the effects of EST on wound healing outcomes were described and appraised. A total PRISMA score was assigned for each included SR based on criteria included in the assessment of multiple systematic reviews (AMSTAR) measurement tool. The percentage of available research that was identified in the SR was also calculated.

Results: Sixty-two clinical research studies involving 2082 patients with pressure ulcers, venous leg ulcers, diabetic foot wounds, and arterial/ischemic wounds, and ulcers of mixed etiology were located. Thirty-three of the studies with 1370 patients compared wound size reduction after EST to a control group. Eighteen reviews that used a systematic approach to identify, select, and evaluate published studies on this topic have yielded conflicting results. Poorer quality SRs with a low total PRISMA score were more likely to yield negative or inconclusive findings. Most of these low-quality SRs had very vague research questions and included less than 50% of the available literature that was known to exist. Results from 22 well-designed randomized clinical trials and 10 high-quality SRs consistently support that EST can stimulate faster wound size reduction and/or produce a greater number of closed wounds compared to a group of similar patients receiving either standard wound care or sham EST.

Conclusion: Pooled results from well-conducted SRs provide strong support for the use of EST on various types of chronic wounds and pressure ulcers in particular.

Keywords: electrotherapy, pressure ulcer, venous ulcer, diabetic foot ulcer, wound healing, systematic reviews

Introduction

Electrical stimulation therapy (EST) is an adjunctive therapy designed to deliver low levels of electrical current to tissues in and around the open wound.¹ There are two or more oppositely charged electrodes placed on the surface of tissues which are composed of a variety of materials and come in different shapes and sizes. Some electrodes are custom designed for wound care, while others have been modified from other clinical uses. Different types of current (direct current, pulsed current) and a range of stimulus parameters (duration, frequency, amplitude) can be selected to deliver electrical energy to the wound; in most instances, the current is unbalanced such as high-voltage

pulsed current (HVPC), and creates a small charge beneath the electrode.

Electrical energy is used for several clinical indications; for example, electrical activation of nerves and muscles is often employed in physical rehabilitation settings to modulate pain (called transcutaneous electrical nerve stimulation), activate muscles (neuromuscular electrical stimulation [NMES]), and/or restore function (functional electrical stimulation [FES]). Therefore, EST for wounds is often described by clarifying what it is not. In addition, some devices initially designed for other purposes have been purported to indirectly promote wound closure.²⁻⁴ Another form of electrotherapy uses high-frequency radio waves (MHz) to generate electrical fields within wounded tissues – termed pulsed electromagnetic fields (PEMFs). PEMFs are generated via a single coil electrode that does not have to be placed in contact with the skin and induces the movement of electrically charged molecules (such as electrolytes) in the local region. Since these other forms of electrotherapy are relatively new, clinical and experimental research is scarce, and it is not known if they have similar effects on healing as EST. Unfortunately, few reviews define exactly what is meant by EST, and therefore, different forms are combined.⁵

EST is not a new therapy. Rather, the first report that described that low levels of electricity can be harnessed to stimulate tissues in the wound bed and periwound skin and promote wound closure was published in 1968.⁶ Since these initial reports, over 60 clinical reports and several hundred experimental studies have investigated the effect of EST on tissue repair processes.

Several best practice guidelines (BPG) have been directed toward the management of common types of wounds such as pressure ulcers, venous leg ulcers (VLUs), and diabetic foot wounds.⁷⁻¹⁵ BPG panels with international and interprofessional representation have reviewed research related to a particular wound type and often assigned EST the highest level of research evidence and strongly support the use of EST in clinical practice.⁷⁻¹² Some BPGs have not recommended EST because of the conflicting results that have emerged from a plethora of recent systematic reviews (SRs).¹³⁻¹⁶

SRs and meta-analyses

SRs and meta-analyses were introduced relatively recently as a novel research methodology that could help busy clinicians to stay abreast with current research trends.¹⁷ An SR is a review of a clearly formulated question that uses systematic and explicit methods to identify, select, and critically appraise relevant research, and to collect and analyze data from the studies that are included in the review.¹⁷ An SR is

said to be well designed if it addresses a carefully crafted question, employs an objective and comprehensive search of the literature, applies predetermined criteria to select relevant articles, and critically appraises the included studies. When these steps are undertaken, all relevant research published within the dates set out in the review should be included.

Meta-analysis refers to the statistical method used to synthesize results from a series of included studies.¹⁸ It requires an SR be completed initially to identify relevant and similar studies. If, and only if, the included studies have used a similar outcome measure, then results can be pooled, and an overall treatment effect can be estimated. When the pooled result is in favor of the intervention, it is considered the highest level of research evidence to support implementation of the treatment/intervention into clinical practice. The ability to combine smaller research studies allows researchers and clinicians to consider a body of evidence rather than a single multicenter trial. Correspondingly, meta-analyses and SRs are considered a higher level of evidence than a single large-scale randomized controlled trial (RCT).¹⁹ Compiling results via meta-analyses is also a practical way to evaluate the efficacy of treatment interventions rather than the more expensive and lengthy multicenter trials that are really only feasible when supported by large industries. These large-scale studies that involve hundreds of subjects are seldom feasible, especially for medical devices. The placement of meta-analyses atop the hierarchy of clinical research evidence is dependent on the ability to combine results from several well-conducted clinical trials. Many studies that set out to do a meta-analysis are unable to calculate an overall effect for a particular intervention because similar outcome measures are not consistently employed. Needless to say, these methodologies that synthesize research are only as good as the clinical research that has been previously published in the field. In the wound healing field in particular, most of these reviews have yielded results that are inconclusive and author's call for further research to be conducted. Tricco et al identified a total of 99 SRs that examined interventions/practices that were used to improve healing outcomes in people with various types of chronic wounds.²⁰ They concluded that few treatments were consistently effective across all outcomes in the literature.²⁰

Various scores have been developed to rate the methodological quality of RCTs designed to test the benefit of clinical interventions.^{21,22} Through this evaluation, clinicians have become aware that flaws can exist in published research and that it is no longer assumed that all clinical trials are created equally. However, the same critical appraisal is not always applied to SRs and meta-analyses. As more SRs are

published, greater disparities are found, and conflicting results are produced. This can be confusing to clinicians and panel members who are tasked with developing/updating best practice guidelines since they are unsure how to interpret the findings. This is particularly true in the case of the research that has evaluated advanced/adjunctive therapies designed to speed up the closure of chronic wounds.

An international panel of experts was convened in 2007, and using an established consensus process, developed a list of eleven key criteria of SRs and/or meta-analyses. A measurement tool for the “assessment of multiple systematic reviews”²³ (AMSTAR) has been used by others to objectively appraise the quality of published SRs and meta-analyses²⁰ – termed herein as the PRISMA score since it reflects “Preferred Reporting Items for Systematic Reviews and Meta-Analysis”.¹⁷

Purpose of this study

The overall objective of this study is to identify and appraise existing clinical research that has examined the effect of EST on wound healing outcomes in adults with various types of chronic wounds.

Specifically, the review

1. compiles all research studies involving human subjects published before 2016 which have evaluated the effect of EST on wound healing of various chronic wound types;
2. performs a comprehensive literature search to find all the SRs and meta-analyses that have been published to date and evaluate the methodological quality of included reviews using the PRISMA tool;²³ and
3. critically appraises clinical research that has been published for three common types of wounds (pressure ulcers, VLU, and diabetic foot wounds).

This study does not address the large amount of work that has been done regarding mechanism of cellular and physiological effects of E-Stim determined using animal or cellular research. A recent review written by Clark²⁴ with a preface by Keith Harding states that “it is a technology that has significant research underpinning it that we should all be aware of”.²⁵ Readers are referred to a special issue of the journal *Advances in Wound Care* where several articles reviewed experimental research conducted using animal models and in vitro cell studies and described cellular and physiological mechanisms by which EST stimulates tissue repair and wound closure.^{26,27} In brief, EST has been shown to increase tissue perfusion and oxygenation due to increased local blood supply, reduced venous congestion, and enhanced capillary branching and angiogenesis. EST can also promote

inflammation by enhancing white blood cell migration and infiltration into the site of injury (galvanotaxis), increasing the synthesis and release of chemical mediators, and enhancing phagocytosis and natural debridement of foreign and necrotic material. The application of EST to healing wounds stimulates collagen synthesis and organization that promotes deposition of new granulation tissue and creates better wound strength. EST-induced activation of reepithelialization and wound contraction have also been elucidated using both in vivo and in vitro experimental models.²⁷ Collectively, this body of research shows that EST influences healing process via several mechanisms that are active in virtually every phase of tissue repair.^{26,27}

Methodology

Five databases (CINHAL, PubMed, Medline, Embase, Scopus) were searched from inception to October 2016 for articles that met predetermined criteria. Table 1 provides a list of specific inclusion and exclusion criteria. An experienced librarian was contacted to develop a search strategy with a comprehensive list of keywords and MeSH terms. Briefly, these English-language articles evaluated the effect of EST on wound healing outcomes in subjects with open wounds of specific or mixed etiology, including but not limited to pressure ulcers, VLU and/or arterial leg ulcers, or diabetic foot wounds. Articles included all forms of clinical studies involving human subjects such as case studies, uncontrolled prospective and retrospective cohort studies, RCTs and non-RCTs, SRs, and meta-analyses. Clinical studies that were published in only abstract form, written in another language, or did not use the right type of EST were not included (a description of the types of EST addressed in this study is provided in the “Introduction” section). Each included study was carefully checked to confirm that data was unique, and publications involving duplicate data were identified. Reference lists from all articles identified in the extensive search were retrieved, and any additional studies that met inclusion criteria were included. Articles that were published in peer-reviewed journals as well as within gray literature sources were included.

To be considered an SR or meta-analysis, a clear description of methods used to search, select, appraise, and analyze the articles needed to be provided. Definitions of SRs and meta-analyses are provided in the “Introduction” section.^{17,18} Reviews lacking these details were considered narrative reviews and summarized in text form. All SRs with or without meta-analysis were evaluated using the PRISMA tool.²³ Each of the eleven items listed in the document were

Table I Criteria used to select articles included in this study

Category	Inclusion criteria	Exclusion criteria
Population	Adult Open wounds of any etiology Pressure ulcer Diabetic foot ulcers Venous leg ulcers Arterial or ischemic wounds Wounds of mixed etiology	Incisional wounds Skin grafts
Intervention	Electrical stimulation therapy At least two surface electrodes placed on or near the wound	Electromagnetic fields or other induced electric fields Electrical currents used diagnostically Use of indwelling or spinal electrodes TENS for pain modulation NMES for muscle strengthening or endurance FES for improvement of functional outcomes
Control	Clinical studies involving human subjects Case study Case series Prospective cohort studies Retrospective cohort studies Nonrandomized controlled trials Randomized controlled trials Multisite clinical trials Systematic reviews Meta-analyses	Languages other than English Only abstract available Animal or experimental studies In vitro cell culture studies Narrative reviews published before 2000 Studies with duplicate data
Outcomes	Wound size reduction Wound surface area Wound appearance using valid outcome measures (PUSH tool) Number of healed wounds Time to healing	Blood flow Wound prevention Wound recurrence Pain Quality of life Cost analysis

Abbreviations: TENS, transcutaneous electrical nerve stimulation; NMES, neuromuscular electrical stimulation; FES, functional electrical stimulation; PUSH, pressure ulcer scale for healing.

assigned one point based on whether the required component was explicitly described in the paper. The number of items present was totaled to yield a “total PRISMA score” out of 11. PRISMA scores of 5 or greater indicate well-conducted SRs and meta-analyses. In addition, key methodological flaws such as including studies with duplicate data and combining different forms of EST were identified.

To determine the comprehensiveness of a review, a value for the percentage of available studies was calculated for each included review and/or meta-analysis. The percentage of available studies was calculated by placing the number of studies about EST which were included in the review over the total number of RCTs that are known to be available in the literature during the time frame of the review. To determine the total number of available studies, the inclusion and exclusion criteria set out within the review were considered. Common exclusion criteria reflected in this calculation were type of wounds or patient group, year of publication, study design, and sample size. Since many reviews excluded clinical trials involving less than 10 subjects or without random allocation to groups, these

small studies were seldom included in the total number of available studies. In many instances, the inclusion criteria were not explicitly stated, in which case the authors were given the benefit of doubt.

Results

Original clinical research studies: non-randomized and randomized prospective studies

Research teams from around the world have generated clinical data from a variety of patient demographics, all types of chronic open wounds, and the full spectrum of health care settings.

Table 2 is a summary of controlled clinical trials where E-Stim was used to treat three of the main types of chronic wounds (pressure injuries,^{28–44} venous ulcers and other wounds of the lower extremity,^{45–53} and diabetic and/or ischemic ulcers^{54–60}). This chart of controlled clinical trials does not include three studies that were found to have the same data presented in another publication – referred to as

Table 2 Summary of controlled clinical trials that evaluated the effect of EST compared to control treatments on people with pressure ulcers (indicated as “pressure”), VLU, diabetic foot wounds with or without arterial disease, and ulcers of mixed etiology. For each of the 33 controlled trials, information about the study design, patient group recruited, and EST protocol employed is provided. Calculations made for the average number of treatment hours per week, total number of weeks, and total hours of EST are provided. Results of the between-group analysis are provided, and conclusions drawn by the authors are summarized

Notes: ^aStudy has less than 10 subjects per group. ^bGreater than 50% of enrolled subjects did not complete study evaluation period. ^cPatients were not randomly assigned to treatment groups. ^dEST protocol was not optimal to stimulate healing. “Yes; EST > Con” indicates that wound healing outcomes were significantly better than control wounds. “No; EST = Con” indicates that there was no statistically significant difference between EST- and control-treated wounds. “Yes; EST > SVWC” indicates wound healing rates were significantly better than standard wound care. “No; EST = surgery” indicates EST produced similar wound healing rates as those receiving surgery. “Pulsed” represents asymmetrical biphasic unbalanced pulsed current.

Abbreviations: EST, electrical stimulation therapy; VLU, venous leg ulcers; N, number of patients; CT, controlled trial; TENS, transcutaneous electrical nerve stimulation; RCT, randomized controlled trial; Con, control; LIDC, low-intensity direct current; SCI, spinal cord injury; MENS, microcurrent electrical nerve stimulation (<1 mA); HVPC, high-voltage pulsed current; BiPc, biphasic pulsed current; DC, direct current; SWC, standard wound care; N/A, not available.

duplicate data.^{61–63} Twenty-two of these 33 studies used a prospective randomized study design where wound healing outcomes were collected systematically using valid outcome measures and well over 80% of subjects completed the study protocol.^{29–31,33,34,37,39,42–45,48–57,59} Although data from a control group that did not receive EST was included in the report and analyses, eleven studies had key methodological flaws and were labeled “controlled trial” (CT) since they did not use a random allocation method^{36,38,40} or involved fewer than 10 subjects per group.^{28,35,38,41,46,47,58,60} The majority of the controlled studies involved the use of relatively small number of subjects and seldom were the large-scale multicenter trials coordinated by industry. Most controlled clinical trials enrolled a total of 20–50 subjects, and only eight trials had 60 or more subjects in the study.^{33,37,39,43,50,51,56,57} A couple of studies reported only the number of wounds^{37,64} treated, and some included results from multiple wounds from the same patient.^{33,39,42,49,57,65,66}

EST was delivered in a variety of ways to tissues surrounding the wound, or directly into the wound bed or both. Most devices used to deliver EST provided pulsed current via small battery-operated devices. Initial research used low levels of direct stimulation called low-intensity direct current.^{31,40,59} A few recent reports have employed innovative technologies to deliver very low levels of EST directly to the wound bed through small devices incorporated within the dressing.^{32,33} The remaining included studies, listed in Table 2, which used pulsed current of different designs that delivered short-duration pulses (microsecond duration) at rates between 10 and 100 times per second. Some researchers have claimed that biphasic pulsed current which flows in two directions during the treatment, is less effective than monophasic (or unidirectional current) including HVPC.⁶⁰

Treatment duration ranged between 30 and 75 minutes per session. Ahmad evaluated the effect of increasing the treatment period from 45 to 60 and 120 minutes.⁴³ Most treatments were repeated three to seven times per week and based on dressing change schedules. Wound outcomes were evaluated after several weeks of treatment ranging between 3 and 8 weeks. Longer treatment times (lasting 12 weeks) were more commonly used for people with arterial ischemic wounds,⁵⁸ diabetic foot wounds,^{55,56} or spinal cord injury (SCI)^{42,44} or when very low levels of current (microcurrent electrical nerve stimulation, MENS) were used.³³ This wide range of treatment duration is consistent with studies where EST treatments were given until wound closure and the average time to heal ranged between 3 and 14 weeks.^{38–40,57,60}

All but eight studies detected a statistically significant improvement in at least one wound healing outcome after E-Stim treatment compared to a similar control group.^{28,32,33,39,45–47,53,57} Seventeen of 22 well-designed randomized clinical studies found that EST produced faster healing or led to shorter time to closure than controls. Negative findings predominated in studies with small sample sizes (less than 10),^{28,46,47} where very low-intensity EST (MENS) was used,^{32,33} or EST was delivered at a distance from the wound, or where EST protocols were suboptimal.^{45,53} Ogrin et al⁴⁵ performed a double-blinded, randomized, controlled clinical trial; however, the EST treatment was suboptimal since treatments lasted only 5 minutes in duration. Katelaris et al⁵³ also used an EST protocol that was not conducive to healing since they combined EST with providine solution, and found that when EST was added to providine, wound size actually increased. In addition, there are concerns with two studies performed by Baker et al in which a similar design was used to evaluate the effect of three different EST protocols on individuals with

diabetic foot ulcers (DFUs)⁵⁷ or people with SCIs.³⁹ While a large number of participants were recruited into these studies, it was only after data was modified to include only those with good compliance and by combining MENS-treated individuals with control group that statistical differences were found between groups. Therefore, in this study, the original data analyses were considered for both studies performed by Baker et al, and no effect of EST was recorded.

Several reports document the benefits and safe application of EST on specific cases with very challenging wounds^{6,64–77} and other noncontrolled retrospective^{78,79} and prospective research designs.^{80–85} Two of the original clinical reports are often identified as controlled studies since they included a relatively large number of subjects; however, they compared healing outcomes produced after EST to only six patients with bilateral wounds.^{86,87} Goldman et al^{58,79,88,89} have produced a number of very compelling reports where EST was used to treat patients with ischemic wounds of the leg and foot often complicated by diabetes. They showed repeatedly that daily treatments with EST progressively increased local tissue perfusion and increases in transcutaneous oxygen pressure measurement (TCPO2) were associated with less pain and

better healing outcomes. There are also two larger studies with historical controls which describe improved healing outcomes that can be achieved when EST is applied as part of standard clinical practice.^{78,90}

Collectively, the effects of EST on healing have been evaluated in over 2000 subjects and published in a total of 62 articles in peer-reviewed journals since 1968 (Table 3). In 33 of these clinical reports involving 1370 subjects, healing outcomes of an EST-treated group were compared to an appropriate control group. Unfortunately, eleven of the 33 trials were considered of poorer methodological quality.^{28,35,38,40,41,46,47,50,53,58,60}

Research that focused on pressure ulcer treatment using EST is most common. A total of 27 clinical reports evaluated the effect of EST on people with pressure ulcers,^{28–44,64,67,69–71,74,75,77,79,82,85–87} and 17 of these were controlled clinical trials.^{28–44} This extensive search also identified eleven clinical reports (n=367) that have used EST for the treatment of VLU. Three of these studies^{46–48} included “ulcers of the lower leg” of which the majority were VLUs. Nine of the included studies (n=361) evaluated the effects of EST on leg wounds compared to a control group.^{45–53}

Table 3 Summary of clinical research reports published about the effects of EST on wound healing outcomes. Clinical research reports include single case reports, uncontrolled prospective and retrospective cohort studies, and controlled (randomized or not) clinical trials. The number of patients and studies that have been published about pressure ulcers, venous leg ulcers, and diabetic foot wounds of mixed etiology is summarized

Abbreviation: EST, electrical stimulation therapy.

While there are 13 studies that focused on wound occurring in people with diabetes, only five were prospective controlled studies with only 212 subjects evaluated.^{54–58} Eleven clinical reports including several uncontrolled prospective cohort studies^{59,60,65,66,72,74,77,78,80,86–88,91} and retrospective analyses⁷⁸ showed that the application of EST to a variety of wound types consistently improved healing outcomes. Altogether, this body of literature provides strong support that EST stimulates generic processes of tissue repair and so is effective on many different types of chronic or recalcitrant wounds.

Narrative reviews

Given the substantive body of literature, there have been several reviews published about either adjunctive therapies in general^{92,93} or EST for wound healing specifically.^{24,91,94–100} Most of the authors of these narrative reviews formulate an opinion that there is a strong research support for the use of EST to stimulate wound healing and promote wound closure.^{24,94,96,98,99,101} However, some reviewers conclude that research is lacking, conflicting, and/or inconclusive.^{92,93,97,100} Collectively, over 54 clinical reports have been identified by retrieving all the references cited in these reviews. To describe each of these articles in detail is beyond the scope of this study. Readers wishing to find detailed description of all the clinical studies where EST has been used to speed healing or wound closure should refer to comprehensive reviews that addressed all types of wounds.^{94,97–99,101–103}

Critical appraisal of SRs and meta-analyses

Table 4 outlines the details of 18 reviews that have been published in the literature on the effect of EST on wound healing.^{5,10,14,15,104–116} Eight of the reviews completed at least some form of meta-analysis.^{10,15,104–109} Three other reports stated that although a meta-analysis was planned, none was done because of heterogeneity of included studies.^{14,112,113} The first SR published on this topic was produced by Gardner et al in 1999, and impressively, it also included a meta-analysis.¹⁰⁹

The results of eleven of the 18 included SRs favored the use of EST in the treatment of various types of chronic wounds.^{5,10,102,104,105,107–111,116} The authors' concluding statements regarding EST use in wound treatments obtained from each review are presented in Table 4. In four reviews, the authors' recommendations suggested that there was no evidence to support routine clinical use of EST for wound therapy.^{14,112–114} Three other reports felt that research was inconclusive.^{15,106,115} It is understandable with the variety of conclusions that clinicians become confused and feel that this area of research has

conflicting results. However, if the proportion of available research that was considered and quality of the review is assessed by the PRISMA tool, then a clear trend emerges. All but two^{15,106} of the nine higher quality SRs (with greater than five of eleven items on the PRISMA tool present) found results in favor of EST over standard care, whereas most of the lower quality SRs did not recommend using EST in clinical practice because results were either lacking^{14,112–114,116} or conflicting.¹¹⁵

An obvious reason why there is inconsistency across SRs published about the use of EST for treating chronic wounds is that the studies included in each review are quite different. These differences can sometimes be explained by the research question that is defined by each review. Correspondingly, specific inclusion and exclusion criteria are used to define the scope of included studies and to focus on a particular patient population or wound type. To address this issue, the percent of available literature was calculated (Tables 5–7). Even when the inclusion criteria set out by the review were considered, only eleven of 18 published SRs considered the majority (>50%) of clinical trial studies available in the published literature.^{5,10,102,105–110,115,116} In some instances, the inclusion of a relatively low proportion of available studies was explained by the authors' decision to only examine clinical reports published during certain years. Without explanation, two SRs^{14,112} chose not to include any clinical research published before the year 2000 which unfortunately resulted in the exclusion of 18 of possible 33 CTs. It is not clear why the review by Health Quality Ontario¹⁵ described an extensive search strategy and found only 34% of available articles. However, this low rate of article retrieval does explain why their results were inconclusive.¹⁵

Another issue in these reviews was that reviewers failed to detect that the same data was presented by authors in two separate publications – called duplicate data. There are three instances where identical data was presented for an EST group – Mulder⁶¹ and Feedar et al²⁹ in 1991; Trontelj et al⁶³ and Jercinovic et al³⁷ in 1994; and Karba et al⁸¹ in 1990 and Karba⁸⁰ in 1991. While less obvious, given the same time frame and similar treatment groups, it was assumed that similar data was included in the publications by Franek et al in 2005⁶² and again in 2006⁵¹ and the retrospective data presented by Stefanovska et al in 1993³⁶ and Cukjati et al in 2001.⁷⁸ While Lala et al excluded duplicate publications,¹⁰⁸ this was not picked up by three other reviewers.^{5,102,106} In the present study, data was used only once to calculate total number of published studies and total number of subjects (Table 3).

Discussion

The PRISMA tool was used to provide a systematic approach of evaluating the methodological quality of the SR²³ (Table 4). A review with a total PRISMA score of 5 or less out of 11 was considered low quality. This approach is consistent with work of other authors.²⁰ Admittedly, certain features, such as the comprehensiveness of the search, may be considered more important than other components such as declaring any conflict of interest and providing a list of excluded studies. The ability to include a list of excluded studies is sometimes beyond the control of the authors. Since all but one of these reviews¹⁵ were published in peer-reviewed literature, conflict of interest is often addressed. Publication bias was seldom addressed in these SRs; only one review provided a funnel plot.¹⁰⁵ This is not surprising since it is a relatively new concept in this field.¹¹⁷

In most instances, studies with low total PRISMA scores and also included less than 50% of available studies published during the time frame were included in the review (Table 4).^{14,111–114,116} Additionally, five of seven lower quality SRs^{14,112–116} concluded that either EST was not effective in the treatment of chronic wound or results were inconclusive.¹¹⁵ SRs that evaluated the effect of EST on all types of chronic wounds were generally well done and included the majority of available research that had been published at the time of the review.^{102,104–106,109} Only one of the eight SRs that focused specifically on the effects of EST or other physical modalities, did not support the use of EST for wound healing.¹¹⁴ In the Cochrane review published in 2001, because of different outcomes measured at several time points, the meta-analysis evaluating the pooled effect of EST included only one RCT.¹⁰⁶ The Cochrane Wounds group tends to make conclusions very conservatively. In fact, only two wound care interventions have been recommended by Cochrane in the past 35 years. The review produced by Koel and Houghton was rated low quality since points were only assigned if the component was clearly described in the text of the paper.¹⁰⁴ Given that this was an invited review, methodological details were not included. As a coauthor of this meta-analysis, I can state that a very rigorous methodology under the direction of the Cochrane Wounds group was undertaken to select, evaluate, and collate data from included studies.

Ten of 18 reviews that were retrieved addressed pressure ulcers,^{5,10,14,15,104,108,110,111,113,114} and two reviews looked at chronic ulcers occurring in people with diabetes.^{107,112} A list of included SRs and meta-analyses is provided in Table 4. Surprisingly, only one SR published to date has focused on VLUs.¹¹⁵ Four meta-analyses and one SR evaluated the

effect of EST on healing outcomes for all types of chronic wounds.^{102,104–106,109} Within the five reviews that addressed all types of chronic wounds (Table 4), four focused specifically on the effects of EST^{102,104,105,109} and localized more than half of the available literature. Further, all four reviews that focused on the effect of EST but included any type of chronic wound produced results in favor of EST. One meta-analysis published by Barnes et al was particularly well done in that it addressed ten of eleven key items considered essential by PRISMA, and the extensive search identified 20 of possible 26 articles that were published at the time.¹⁰⁵

A total of ten reviews included in this study evaluated the effect of EST on pressure ulcers (Table 4). The objective of many of these reviews was to examine not just EST, but all pressure ulcer treatments including dressings, novel technologies that addressed underlying causes, and a wide range of adjunctive therapies (skin substitutes, growth factors, and physical agents). Three SRs focused specifically on pressure ulcers in people with SCI^{5,108,111} reflecting the relatively large number of CTs included those with SCI.^{32,35–44} In some reviews, the authors considered both preventative measures and treatments for pressure ulcers.^{5,111,114} This is a huge body of literature to consider and therefore understandable that most of these expansive reviews did not consider the full body of literature available for EST. Results presented in Table 4 demonstrate that reviews that were not conducted according to the PRISMA guidelines do not consider the majority of studies published about EST, and resulted in conclusions that do not favor EST. In fact, many of these poorly conducted SRs take on expansive topics and end up without recommending any intervention for the management of pressure sores or DFUs. What is most unfortunate is that many of these faulty reviews were developed by national wound care societies and used to direct best practice guidelines for wound care.^{14,16} An exception to this case was an SR performed by Smith et al in 2013 which was used to inform the Agency for Health Care Policy and Research guidelines.¹⁰ The scope of this study encompassed all “adjunctive technologies related to pressure ulcer treatment” including dressings, skin grafts, growth factors, and adjunct therapies. The methods addressed most aspects of the PRISMA guidelines, and therefore, the total PRISMA score was 10 of 11. They concluded that “moderately consistent results from one good and eight fair studies showed that EST improved healing rates”.¹⁰

Only two SRs examined the clinical research published to date regarding the effect of EST on diabetic foot wounds (Table 4).^{107,112} Hinchliffe et al¹¹² included very few of available studies, and the total PRISMA scores were

Table 4 Details about systematic reviews that searched and summarized clinical research that examined the effects of EST on wound healing outcomes in pressure, venous, diabetic, and mixed wound types. Each systematic review was evaluated and assigned a total PRISMA score, and the percentage of available articles that were included in the review was calculated. Conclusions of study authors are provided

Notes: N/A – data not available; PrU – pressure ulcers; PrU-SCI – pressure ulcers occurring in people with SCI; ALL – all types of wounds. SR – systematic review was conducted; Meta – both systematic review and meta-analysis were performed; Y – Yes, the method was conducted; N – No, there was no mention of that step in the systematic review. Total PRISMA score = sum of 11 key steps in systematic review and meta-analysis that were performed; % of available literature = the number of included studies divided by the total number known to be published within the search dates; Results favor EST: Yes – overall treatment effect favors EST or majority of included studies reported improved healing outcomes after EST treatment; Results favor EST: No – no significant differences were detected in EST- vs control-treated wounds. ? indicates results were inconclusive.

Abbreviations: EST, electrical stimulation therapy; SWC, standard wound care; RCT, randomized controlled trial; DFU, diabetic foot ulcer; EPA, electrophysical agent; HVPC, high-voltage pulsed current; SCI, spinal cord injury; PAR, percentage area reduction; HBO, hyperbaric oxygen therapy; NPWT, negative pressure wound therapy; PEMF, pulsed electromagnetic field.

correspondingly low. As a result, the International Working Group on the Diabetic Foot guidelines state “no support exists for any intervention used to speed healing of diabetic foot wounds”. In another more focused review, Kwan et al¹⁰⁷ identified all the available literature (100%) and addressed key methodological issues (total PRISMA score = 8). Results were pooled from three RCTs that evaluated the influence of EST on the number of healed DFUs and found a significant odds ratio in favor of EST.¹⁰⁷ As a result, they concluded that there was potential for using electrotherapies in the management of foot ulcers that occur in people with diabetes.¹⁰⁷

One review addressed the effects of interventions used in the treatment of venous ulcers.¹¹⁵ Thakral et al actually produced two reviews about VLU treatments;^{95,115} however, only one had methods describing an SR process.¹¹⁵ Unfortunately, the narrative review included more of the available literature, while the SR cited only two out of a possible seven CTs that had been published at the time of the review. Since there are several well-designed clinical studies that have evaluated the effect of EST on venous ulcers or ulcers of lower limb, future SRs and meta-analyses that pool the results of this body of work are warranted.

As stated in PRISMA guidelines, an extensive search is needed to be confident that the review includes all of the available literature.²³ These include at least two electronic databases which should be checked by at least two independent reviewers.²³ In addition, secondary sources such as the reference lists of included studies should also be viewed, and

in some instances, hand-searching of relevant journals should be done.²³ Last but not least, gray literature (not published in peer-reviewed journals) should be included. In all cases, the selection and exclusion of relevant articles should be checked by at least two reviewers acting independently, and discrepancies decided by consensus.²³ There is a huge number of terms that have been used to name EST for wound healing. This diversity in terminology is expected given that EST has been around for over 50 years and been investigated by researchers located across the world, many of whose first language is not English. Therefore, the search strategy used to find all articles using EST must be developed with by those who have a firm understanding of this modality. Electronic search must include several keywords and MeSH terms that reflect the full range of terms used to name EST. Inclusion and exclusion criteria need to be clearly defined, since electrical currents are used for many other indications including wound prevention. Checking reference lists from included studies and recent narrative reviews is an essential component of any SR on this topic. In addition, any well-conducted SR should include a search of unpublished and gray literature. The challenge in searching for all relevant research related to EST used for wound healing is likely the underlying reason why many published articles are missed and why inconsistent conclusions are drawn from SRs that have addressed this topic.²⁰

The most common criticism about clinical studies evaluating EST is that sample sizes are too small. This is certainly the case with clinical studies that have less than

Described inclusion	Method quality	Conclusion	Meta-analysis	Publication bias	Conflict	Total	% of available literature	Results favor EST	Authors' conclusions
N	Y	Y	N/A	N	Y	5	25	No	We do not know if electrotherapy improves healing of people with PrU
Y	N/A	N/A	N/A	N	Y	4	77	N/A	Utilization of EST in VLU has not been fully explored. Despite small sample size, EST showed positive results and promise as an option for adjunct therapy
N	N/A	Y	Cannot	N	Y	4	33	No	There does not exist evidence of the efficacy of physical treatments sufficing to establish recommendations for their use in pressure sore treatment

10 subjects per group. Eight controlled clinical trials in this study contained three to nine subjects per group (Table 2).^{28,35,38,41,46,47,58,60} Studies that have sample sizes this small lack the power to accurately detect statistically significant differences between groups. Indeed, studies with less than 10 subjects in a group included in this study were equally likely to have either positive^{35,38,41,58,60} or negative^{28,46,47} findings. To address this concern, several SRs excluded studies with less than 10 subjects per group.^{14,104,115}

According to one study that evaluated the methodological quality of clinical trials, at least 200 subjects should be included in the evaluation; otherwise, the numbers were considered as sparse.¹¹⁴ Clearly, none of the included work meets this mark. Given that EST is a medical device without proprietary property, no industry will fund future research involving “larger scale, multicenter clinical trials”. In fact, several EST devices previously manufactured are no longer available.^{29,30,61,96}

When meta-analyses were first proposed, they were touted as replacing the need for large-scale expensive trials, by combining results from several existing trials in the literature.^{17,21} However, it does require that results are pooled. Of the 18 SRs located (Table 4), only eight did a meta-analysis. Cullum et al used only one RCT in the forest plots,¹⁰⁶ and three other reviews^{14,113,114} stated that clinical difference was too heterogeneous to be combined in a meta-analysis. Conversely, several reviewers undertook calculations so that data could be pooled.^{104,105,108,109} For example, Gardner et al¹⁰⁹ and Lala et al¹⁰⁸ calculated weekly healing rates, and

Koel and Houghton¹⁰⁴ and Barnes et al¹⁰⁵ extrapolated data to determine percentage area reduction at 4 weeks (PAR4). Combining data from studies that evaluated the effects of EST on a particular type of wound resulted in data that was not heterogeneous ($I^2 < 50\%$).

Another common concern raised by reviewers is that studies were too short and subjects were not followed after closure to determine recurrence. Many reviewers propose that future research should examine the effect of wound care interventions on complete healing or wound closure. The validity of surrogate end points such as wound size reduction after 4–12 weeks has been debated previously. Cardinal et al provided compelling data that suggested that PAR4 was strongly correlated with complete healing.¹¹⁸ It is true that only four of the controlled studies for EST examined healing outcomes over 12 weeks or longer. However, several reports reported an average time to healing with EST and control treatments,^{38–40,57,60} and a number of other studies reported the number of ulcers healed in each group.^{28,29,31,32,35,39,44,48,52,55–57,60} What healing outcome is measured and how long the intervention is applied should be dictated by the study question and be reflected in the study design, both of which would be quite different when looking at ulcer healing vs ulcer recurrence. One also needs to recognize that study protocols that evaluate subjects for several months to a year will have high drop-out rates. This was the case in the study by Adunsky et al, where subjects were followed for 147 days; however, the drop-out rate at the final data point was over 50%.³²

Some reviewers indicate that there are serious methodological flaws within the published literature, while others assign this area of research a level 1 evidence.^{10,110,111} Common flaws identified in study designs included a lack of blinding, no description of randomization or concealment methods, and/or no intention-to-treat (ITT) analysis. With regard to concerns about the randomization process, this was likely due to poor reporting rather poor methodology, since many of the clinical trials were published well before the

assessment tools evaluating RCT designs were developed. Similarly, ITT analysis is a relatively new concept that only more recent studies have included. Many reviewers identify that research evaluating the effect of EST has inadequate blinding of participants and researchers. Given the nature of EST, this criticism seems unreasonable. EST protocols described in the literature would result in a sensation under the active electrode or produce a visible muscle twitch, both of which make deriving a placebo or sham treatment virtually

impossible. In addition, the outcomes used to measure healing such as a reduction in wound surface or wound closure are very objective and not likely influenced by rater bias.

Lastly, many reviewers call for a single optimal treatment protocol for ESTs. This suggestion likely stems from other technologies used in wound care which are produced by the same company. The expectation that one device will be produced by industry to meet the range of needs of clinicians and patient groups is unrealistic. Admittedly, there is a variety of waveforms, electrode placements, and treatment schedules that exist in published research (Table 2). This is not entirely surprising considering that this research has been gathered over 50 years and produced by researchers across the world using equipment produced by many different manufacturers. While many parameters can be selected, it has been shown that most EST protocols produce an electrical charge within a fairly small therapeutic range (300–700 $\mu\text{C/s}$).¹ Furthermore, a recent review that evaluated different waveforms used to treat wounds showed that various forms of pulsed current can be used effectively, whereas ultralow intensities of EST have not consistently shown accelerated healing.⁹⁴

Treatment schedules also vary greatly across clinical research about EST. Total treatment time calculated for each study did not suggest that there was any relationship between time EST and rate of healing produced (Table 2). Ahmad⁴³ directly compared the effect of changing treatment times and showed that increasing treatment time from 45 to 60 minutes a session produced faster healing rates; however, further increasing treatments to 120 minutes per session did not result in any difference in healing. Thus, a maximum healing rate seems to be achieved after relatively short exposures. Any studies with longer treatment times⁴⁴ do not necessarily produce faster or more complete healing. The duration of treatment (in weeks) seems to be more related to the type of wound treated with more resistant wounds (SCI, diabetes with or without ischemia) requiring longer treatments.

Evaluating the appropriateness of ESTs should be considered as part of the review of methodological quality. Most tools that assess the quality of a clinical trial examine only aspects of study design and do not address problems with EST. There are overt examples of inappropriate ESTs in this body of literature. For example, Ogrin et al only applied treatments of 5-minute duration, whereas most treatments are applied for at least 45 minutes.⁴⁵ Katelaris et al combined EST with an ionic solution known for its cytotoxicity (providine solution).⁵³ Apart from these two studies, there is a variety of approaches and types of electrical currents that can be used

successfully to treat wounds. A benefit to this variety is that various different devices can be used and electrodes can be placed in or around the wound, and treatment schedules can be modified to fit the patient and family preferences and schedules. It provides clinicians with different ways to meet the patient's needs and potentially increases adherence to the treatment protocol. This level of customization of many features of EST does require that clinicians using it are knowledgeable about the treatment and take the necessary training to ensure that they apply it in a safe and effective manner.

Summary

Within this critical study on EST used in the treatment of chronic wounds, all relevant articles have been compiled. A list of 33 controlled clinical trials is provided which include 22 well-designed controlled clinical trials involving 1370 patients. Several case studies, prospective and retrospective cohort studies, and controlled clinical trials have been published on this topic over the past 50 years. Most of the research completed to date involve patients with pressure ulcers; however, emerging research has investigated if EST can benefit people with other types of wounds including DFUs and VLUs.

A total of 18 SRs and/or meta-analyses have pooled studies that have evaluated the effectiveness of EST on wound healing outcomes. Conclusions derived from these reviews have been conflicting. An evaluation of methodological quality of each review and determination of the proportion of available literature that was considered in the review revealed an interesting trend. Poorer quality SRs that did not address the majority of key items set out by the PRISMA statement¹⁷ were more likely to result in inconsistent or inconclusive findings. These low-quality SRs often had very vague research questions and tried to assess the efficacy of a large number of interventions used in wound care. Having such an expansive body of literature to review resulted in retrieving a very low proportion of clinical research studies that are known to be available in the published literature.

There is clear and consistent research evidence to support the use of EST for wound healing when the results from 22 well-designed RCTs and 11 SRs with PRISMA scores above 5 are considered. Pooled results from well-constructed reviews provide strong support for the use of EST on all types of chronic wounds in general, and pressure ulcers in particular. There is only one well-designed SR that supports the use of EST on diabetic foot wounds and no good review that has compiled the research that is known to exist for EST of VLUs.

Common recommendations for future research in this field include performing more robust clinical research that has greater sample sizes and longer treatment times so that complete wound closure is achieved. Development of single EST protocol that produces optimal treatment outcomes for types of wounds has also been recommended. However, these recommendations may not be realistic. Rather, additional research that evaluates the effect of EST on pressure ulcer may not be needed. Properly designed clinical trials with randomization, valid healing outcomes, and ITT analysis are needed to determine if EST can accelerate healing rates of diabetic foot wounds and ischemic ulcers. Well-conducted and comprehensive reviews that pool results across all the available research regarding the effects of EST on healing of VLUs are also needed.

Clinicians and wound care experts tasked with considering the research evidence as they develop clinical practice guidelines need to consider not only the results of relevant SRs and meta-analyses but also the methodological quality of these reviews. Not all SRs are created equal, and the quality and comprehensiveness of the reviews can often explain inconsistent findings and conflicting conclusions.

Chronic Wound Care Management and Research

Dovepress

Publish your work in this journal

Chronic Wound Care Management and Research is an international, peer reviewed, open access, online journal publishing original research, reviews, editorials, and commentaries on the causes and management of chronic wounds and the major issues related to chronic wound management. Topics also include chronic wounds as comorbidities to other

conditions, patient adherence to therapy, and the economic burden of chronic wounds. The manuscript management system is completely online and includes a very quick and fair peer review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/chronic-wound-care-management-and-research-journal>
