Abstract: Patients undergoing arthroplasty or other orthopedic surgery show a high risk of venous thromboembolism (VTE), involving mortality, morbidity, and social costs; however, the risk for VTE in minor orthopedic surgery should not be underestimated and antithrombotic prophylaxis may be required. According to the literature, low-molecular-weight heparins (LMWHs) are more effective in preventing VTE than unfractionated heparins (UFHs) or vitamin K antagonists, and have a lower hemorrhagic risk. By comparing different prophylactic regimens, it has been shown that starting the prophylaxis near the time of the operation is the most critical point for efficacy, whether or not the first dose is administered pre- or post-operatively. Moreover, most thromboembolic complications are observed after discharge and, therefore, many clinicians advocate continuing prophylaxis for longer times (6–8 weeks) in order to further reduce the rate for VTE. The literature on parnaparin, a new LMWH, in VTE prophylaxis was reviewed. Parnaparin is equally effective as UFH, but it offers the advantages of a once-daily administration and improved tolerability, thus allowing the home management of patients with no need for laboratory coagulation tests.

Keywords: orthopedic surgery, low molecular weight heparins, antithromboembolic prophylaxis, parnaparin

Prophylaxis of venous thromboembolism

Patients undergoing elective arthroplasty (hip or knee) or other major orthopedic surgery are at high risk of developing venous thromboembolism (VTE), which represents a dangerous event in terms of mortality and morbidity with high social impact and costs.

Randomized clinical trials (RCT) estimate that, in absence of a thromboprophylaxis, the incidence of venographically proven VTE ranges from 45% to 57% after total hip replacement (THR) surgery, 36% to 60% after hip fracture surgery (HFS), and 40% to 84% after total knee replacement (TKR) surgery (Geerts et al 2001; Geerts et al 2004).

Although low-dose unfractionated heparin (UFH) (Collins et al 1988) and aspirin (Antiplatelet Trialists’ Collaboration 1994) have been reported more effective than no prophylaxis in patients undergoing THR, these agents have been abandoned today in favor of low-molecular-weight heparins (LMWHs), vitamin K antagonists, and synthetic derivatives of factor Xa inhibitor, such as fondaparinux.

In fact, several studies (Chiaipuzzo et al 1988; Mascali et al 1988; Planes et al 1988; Pini et al 1989; German Hip Arthroplasty Trial Group 1992; Colwell et al 1994; Haas et al 2006) and meta-analyses (Nurmohamed et al 1992; Freedman et al 2000; Koch et al 2001) have confirmed that LMWHs are more effective than low-dose or adjusted-dose UFH with a relative risk reduction of 25%–50%. Moreover, LMWH are as effective as vitamin K antagonists in the VTE prevention, but they have a lower hemorrhagic risk (Imperiale and Speroff 1994; Palmer et al 1997; Fitzgerald et al 2001;
While the prophylactic efficacy of LMWH is today unquestioned, the treatment schedule (when to begin, how many times a day, and for how long) is a still debated point. The standard protocols in North America recommend the administration of a first LMWH dose between 12 and 24 hours after surgery, whereas in Europe the prophylaxis is often begun pre-operatively (10–12 hours before surgery) (Strebel et al 2002). Several authors have compared different prophylactic regimens in order to ascertain whether the first dose is more effective if given pre- or post-operatively. It has been shown that starting the prophylaxis near the time of the operation is the most critical point, whether or not the first dose is administered pre- or post-operatively (Laguardia and Caroli 1992; Strebel et al 2002; Bandiera et al 2003; Raskob and Hirsh 2003). A review of RCTs has shown a reduction of 40%–50% in the DVT rate in THR patients when the prophylaxis was begun between 2 hours before and 8 hours after surgery, although the pre-operative administration of heparin seemed to involve a higher hemorrhagic risk (Hull et al 2001). The risk can be reduced, however, by giving an early post-operative (6–8 hours) low dose of heparin, and by increasing the doses of heparin in the following 24 hours or later, according to the course of post-operative bleeding (Hull et al 2000; Geerts et al 2004).

On the other hand, the risk for TVE is not confined to the immediate post-operative period. According to literature, most of symptomatic TVE complications (12%–35%) occur after discharge; thus, several authors suggest that the prophylactic treatment should be continued for longer times (6–8 weeks) whenever risk factors are present, and be stopped only when full weight on the treated limb is resumed. It has been reported that continuation of prophylaxis for at least 2 weeks may further reduce the TVE risk by an additional 50% (White et al 1998; Samama et al 2002; Geerts et al 2004; Goldhaber 2004; Verhaeghe 2005; Arcelus et al 2006; Prejbeanu et al 2007).

Finally, the risk for TVE in minor orthopedic surgery should not be underestimated even if an antithromboembolic prophylaxis is rarely used in these patients. The presence of concomitant risk factors for thromboembolism, as well as the frequent use of a tourniquet with subsequent revascularization in performing these operations, may explain the high rate of TVE complications in this “minor” surgery. Thus, appropriately long prophylaxis with LMWH is also indicated in these patients (Obermosterer et al 1999; Michot et al 2002; Montebugnoli et al 2007).

### Low-molecular-weight heparins

LMWHs are extracted from UFH of animal origin with a molecular weight (MW) ranging between 4,000 and 30,000 Da. The activity of LMWHs is mediated by their binding to antithrombin III (AT III); however, because of fragmentation, the coagulation factors IIa and Xa are affected differently by AT III and, therefore, the antithrombotic activity is separated by the anticoagulant effect because of a larger anti-Xa activity compared with anti-IIa activity.

The structural changes in LMWHs modify the pharmacokinetics compared with UFH: the absorption after subcutaneous (sc) administration is almost complete, predictable, and reliable. The smaller molecules have a lower binding to plasma and tissue proteins and, consequently, a higher antithrombotic activity is available in the plasma; moreover, LMWHs undergo reduced liver metabolism and have an increased renal elimination. The plasma half-life of LMWHs is therefore longer than that of UFH, although to varying degrees among different molecules, thus allowing for a single daily administration.

The anti-Xa/anti-IIa activity rate expresses the relationship between the doses producing the desired antithrombotic activity, and those producing the undesired anticoagulant effects. This way of expressing the activity of the LMWH has a clinical meaning during DVT prophylaxis, the main objective of prophylaxis being to inhibit the formation and growth of fibrin thrombus at the site of DVT without affecting the systemic coagulation. It is generally recognized that the greater is the fractioning of the AT III-binding chain, the shorter and more homogeneous the synthetic molecule, and the more selective the inhibitory activity on factor Xa compared with factor IIa.

### Parnaparin

Our aim was to review the available clinical data on parnaparin, a LMWH that is effective and generally well tolerated in the prevention of VTE, as well as in the treatment of arterial and venous diseases (McKeage and Keating 2008). The data source was PubMed, which was searched for “parnaparin” or “Fluxum”, returning 4 reviews and 25 experimental works; no restriction on language and time was applied. Moreover, published reports not listed in PubMed were provided by Alfa Wassermann S.p.A. (Bologna, Italy). Dosages of parnaparin reported in this review (3,200, 6,400 and 12,800 IUaXa) were calculated using the chromogenic method from the European Pharmacopoea Standard of LMWH. These units are equivalent to those mentioned in clinical papers from the 1980s through to the mid 1990s.
Parnaparin in orthopedic surgery

Clinical evidence for the effectiveness of LMWH and, especially, of parnaparin, in the prevention of DVT in patients undergoing major orthopedic surgery for arthroplasty and trauma has been published over several years. Prophylaxis with parnaparin has been reported to be more effective than placebo (Valle et al 1988) and more advantageous than UFH. In a series of 140 patients, DVT was detected in legs either by Doppler sonography or $^{125}$I-fibrinogen uptake test in 7.1% and 10% of patients treated, respectively, with parnaparin 3,200 IUaXa sc ($=7,500$ aXaU) twice daily or calcium UFH 5,000 IU sc 3 times daily, given for 7 days (Chiappuzzo et al 1988). In another trial aimed at preventing post-operative VTE after hip fracture, 49 patients were randomly treated either with parnaparin 3,200 IUaXa twice daily or with UFH 5,000 IU tid. Screening for thrombosis was performed with $^{125}$I-fibrinogen leg scanning and strain-gauge plethysmography, and positive results were confirmed by venography. In this study, the rate of venographically proven DVT was 20% in the parnaparin group and 29% in the UFH group. The difference was not statistically significant since the number of randomized patients was rather small, but there was an interesting trend in favor of parnaparin, as 1 pulmonary embolism and 2 deaths occurred in the UFH group, and none in the parnaparin group (Pini et al 1989).

Bandiera et al (2003) performed a multicenter study on 381 patients at high risk of DVT undergoing major orthopedic surgery; they were treated with UFH, parnaparin or other LMWHs, given around the time of surgery and continued at home for 10–90 days according to the type of operation or risk factors. Parnaparin was administered once daily at doses ranging between 3,200 and 4,250 IUaXa/day. DVT was diagnosed clinically and instrumentally (Echo Color Doppler). The authors concluded that LMWHs were significantly more effective than UFH (DVT rate 10.3% vs 16.6%), and that parnaparin was even slightly more effective (DVT 8.4%) than other LMWHs, although a significant difference was not achieved (Table 2).

Moreover, while one case of major bleeding was observed for each treatment groups (ie, UFH, parnaparin and other LMWH), episodes of minor bleeding (such as a local hematoma at the site of injection or surgical wound or a need for a surgical drainage) were observed in 17.85%, 6.06%, and 11.76%, respectively, of UFH, parnaparin, and other LMWH-treated patients. Other adverse drug reactions (ADRs)
(such as pain or irritation at the injection site), were observed in 25.0%, 7.4%, and 32.4% of patients treated, respectively, with UFH, parnaparin, and other LMWHs (Table 3).

The slightly higher antithrombotic activity achieved with parnaparin and other LMWHs compared with UFH demonstrates that a higher level of inhibition of Xa is associated with administration of a LMWH with no increase hemorrhagic risk. Thus, the use of parnaparin appears to be safer in orthopedic prophylaxis, as suggested by Mascali et al (1988), who reported a statistically significant lower incidence of side effects (ie, local hematomas) in parnaparin- than in UFH-treated patients (25.0% vs 64.7%).

The more appropriate time for starting prophylaxis with parnaparin was investigated by Laguardia and Caroli (1992). Forty patients undergoing THR were randomly treated with parnaparin 6,400 IUaXa in once-daily administration starting either 2 hours before or 2 hours after the surgical operation. The treatment lasted 7 days. The results showed that the incidence of DVT was very similar and extremely low in the two groups, only 1 patient in each group having a positive diagnosis on phlebography. Although the sample size was relatively small, the authors concluded that prophylaxis was effective in both groups with a DVT rate approaching 5%, and without any significant difference between groups in the amount of perioperative bleeding.

**Parnaparin in minor orthopedic surgery**

Over the past 20 years, arthroscopy has become an important tool in orthopedics for virtually every joint. Complication rates for arthroscopy are low but not absent (<8.2%), including DVT and PE, whose incidence may be increased either by specific risk factors of patients (such as old age, obesity, and concomitant venous diseases) or by the local ischemia secondary to the use of a tourniquet (Table 4). Thus, the need for prophylaxis in minor orthopedic surgery should not be undervalued (Poulsen et al 1993; Eynon et al 2004; Navarro-Sanz and Fernandez-Ortega 2004).

Clinical studies show that adequate prophylaxis can be achieved with LMWHs (Table 5).

In order to obtain information about the efficacy and safety of parnaparin in minor orthopedic surgery under tourniquet ischemia, we have identified prospectively 509 patients in our center. Knee arthroscopy represented the most frequent surgery (68% of the survey), followed by removal of a fixation device or other foreign material (14%), foot surgery (8.1%), arthroscopy of the ankle and shoulder (1.6%), biopsy (5.1%), and other surgery (3.3%).

The antithromboembolic prophylaxis with once-daily parnaparin (3,200–4,250 IUaXa) was initiated within 6 hours after the end of surgery and extended until full weight bearing and walking was resumed (10.5 ± 9.1 days). All the patients underwent compression ultrasound on days 8 to 10 or with the onset of clinical signs suggesting DVT. Instrumental tests never revealed proximal DVT, while minor bleeding (hematoma in surgical site with hemoglobin decrease <2 g/dL) was found in 7 cases (1.4%) (Montebagnoli et al 2007).

### Other uses of parnaparin

Parnaparin has been also employed for VTE prophylaxis in non-orthopedic surgery. A multicenter study performed by Verardi et al (1988) on 610 patients undergoing general (mainly abdominal) surgery, a statistically significant difference was observed between parnaparin 3,200–6,400 IUaXa once daily and UFH in the rate of post-operative DVT (3.2% vs 6.3%; p < 0.01), although the difference in the incidence of PE between treatment groups did not reach significance (0.3 vs 1.0%).

Parnaparin has been used for VTE prophylaxis in bariatric surgery. Ten severely obese patients (body mass index >50 kg/m²) have been treated with increasing single daily doses of parnaparin (3,200, 4,250, and 6,400 IUaXa) on the three consecutive days leading up to biliointestinal bypass surgery. The highest dose was continued from the day of surgery until day 30 (recovery period). During the pre-operative
In the dosing phase, parnaparin dose-dependently prolonged APTT, with the 6,400 IUaXa dose significantly prolonging aPTT vs the lower doses. Meanwhile, the 4,250 and 6,400 IUaXa once-daily doses increased anti-factor Xa and anti-factor IIa activity. After surgery, 1 patient with heparin resistance experienced pulmonary embolization. No bleeding complications were observed. The dose-response data reported in this preliminary study suggest that parnaparin doses of 4,250 and 6,400 IUaXa may provide effective prophylaxis for VTE in patients undergoing bariatric surgery. However, given the small number of patients, larger, well-controlled trials are required to confirm these findings (Forestieri et al 2007).

Bellosta et al (2007) have compared the effectiveness of nadroparin and parnaparin in the non-prophylactic treatment of DVT in terms of the evolution of thrombosis, in a randomized prospective study in 91 patients. Overall, there were 3 cases (3.3%) of progression of thrombosis despite therapy with LMWH, 2 cases (5%) in the nadroparin group, and 1 case (2%) in the parnaparin group (not significant). The Doppler ultrasound in the follow-up showed a complete resolution of 56% of DVT at an average of 6.1 ± 4.6 months. Valve competence recovered in 65.9% of cases with no significant difference between the two groups.

Parnaparin has been successfully used in the treatment of coronary artery diseases (CAD). Parnaparin 6,400 IUaXa once daily sc for 7 days was more effective than UFH given intravenously for 48 hours, then sc (UFH 5,000 IU every 6 hours) for 5 days in a randomized, multicenter study in patients (n = 897) with unstable angina. The incidence of the triple composite endpoint (death, acute myocardial infarction [MI] or the need for myocardial revascularizations in the 7 days after the start of treatment) was significantly lower in the parnaparin than in the UFH group (7% vs 11%; p = 0.034) (Prime Care Study 2005).

Similarly, in patients with an acute STEMI, sc parnaparin 4,250 IUaXa every 12 hours for 7 days was associated with a lower incidence of a triple composite endpoint of death, acute MI, or the need for myocardial revascularization in the 45 days after the start of treatment than intravenous UFH administered for 3 days followed by subcutaneous UFH 7,500 IU every 12 hours for 4 days (27% vs 42%; p = 0.03) (Wang et al 2006). Moreover, in patients with stable

angina, parnaparin 6,400 IUaXa once daily, together with conventional therapy, significantly increased exercise time compared with placebo (Melandri et al 1993).

Finally, in patients with peripheral arterial obstructive disease a long-term treatment (6–8 months) with parnaparin 6,400 IUaXa once daily significantly improved the pain-free walking time/distance compared with baseline in several studies (Palmieri et al 1988; Mannarino et al 1991; Calabro et al 1993; Simoni et al 1993). The extent of improvement with parnaparin was similar to that demonstrated with UFH in one study (Di Stefano et al 1988).

Tolerability of parnaparin
In humans, a higher rate of post-operative bleeding has been observed to related closely to the dose administered: at a prophylactic dose (3,200–6,400 IUaXa/day) the risk of bleeding is statistically not significant, and in any case lower than that observed with UFH (Martines et al 1990; Bandiera et al 2003). LMWHs do not cross the human placenta and are not detected in fetal blood during the first 6 months of pregnancy (Forestier et al 1984; Ostergaard et al 1989); therefore, they are also safe in pregnant women (Geerts et al 2004; Desai and Suk 2007). Although rare episodes of immunomediad thrombocytopenia due to the use of other LMWHs have been reported (Lecompte et al 1991; Mohr and Lenz 1991), thrombocytopenia related to the use of parnaparin has not yet been observed.

At a local level, the tolerability of parnaparin seems better than that of UFH, with a lower rate of hematomas, pain, and burning in the injection site (Corrado et al 1989; Verardi et al 1989; Mangialardi et al 1991; Della Marchina et al 1993; Bandiera et al 2003; Bellosta et al 2007).

Conclusions
A review of the literature shows that parnaparin, like other LMWHs, is effective and well tolerated when used for prophylaxis of post-operative VTE in orthopedic surgery. Its effectiveness seems to be far superior to that of UFH, and comparable with other LMWHs when initiated pre- or post-operatively near the time of surgery and continued at home for a period depending on the type of operation. Besides the clinical advantages, parnaparin and other LMWHs enable a simpler home management of the prophylaxis since they can be administered once a day and do not require continuous lab tests.

Disclosures
The authors report no conflicts of interest.
