Background: Sickle cell disease is a genetic disorder that leads to abnormally high levels of hemoglobin sickling in erythrocytes. Patients suffer debilitating and severe complications that affect multiple organs, though mainly the liver, gallbladder, spleen, bones, and kidneys. It has a significant impact on morbidity and mortality rates and is associated with substantial health care costs.

Methods: For this study, the researchers prospectively reviewed the charts of 154 sickle cell disease patients who had been treated in Salmaniya Medical Complex hospital in Bahrain between September 2013 and December 2014.

Results: The results obtained showed that 95% of patients had sickle cell hemoglobin type. Of the sample patients, 80% exhibited bone pain, with all patients exhibiting bone crisis. Bio-chemical tests revealed reduced hemoglobin concentration, elevated bilirubin, compromised liver function, and lower white blood cell counts. The incidence of hepatitis B and C was very low, at 0% and 9%, respectively. There were a large number of hospital admissions, with 11 days as an average length of stay. The most common ultrasound findings in this study were hepatomegaly, hepatosplenomegaly, cholelithiasis, gallbladder sludge, and splenomegaly.

Conclusion: Sickle cell disease had profound negative effects on multiple organs, with a particularly large number of complications related to the hepatobiliary system.

Keywords: sickle cell disease, hemoglobin types, bone pain, liver function, hepatobiliary complications

Introduction

Sickle cell disease (SCD) belongs to a group of genetic disorders affecting red blood cells. It is an autosomal recessive disorder caused by a single amino acid substitution – valine for glutamic acid – in the sixth position of the β -globin chain, which gives rise to certain hemoglobin (Hb) abnormalities.¹⁻⁵ It is most prevalent in the tropical and subtropical regions, and 300,000 new cases are being diagnosed annually.^{4,6,7} It has significant effects on morbidity and mortality rates and is associated with substantial health care costs.^{3,8,9}

The sickled red blood cells are a major contributing factor to the development of vaso-occlusion, leading to endothelial damage, anemia, formation of pigment gallstones, cholelithiasis, and multiple organ complications.³ Numerous acute as well as chronic complications occur in SCD, which can manifest as early as the first few months of life.⁸ Among the acute complications, vaso-occlusive crisis, associated with severe pain, is one of the most common and most difficult to manage.⁸ Other

acute complications include acute chest syndrome, acute stroke, priapism, various hepatobiliary complications, splenic sequestration, and acute renal failure.⁸

The spleen, gallbladder, and liver are frequently affected in SCD.¹ Splenic infarction and atrophy are very common and may lead to further complications such as bacterial infections and functional asplenia.¹ The wide range of hepatic dysfunctions that occur in SCD patients are not only a result of the sickling process but also a result of multiple blood transfusions that these patients undergo in their lifetimes.^{9,10} These transfusions may lead to infections such as hepatitis B and/or C, other chronic or acute infections, iron overload, occurrence of pigment stones, cholecystitis, and obstruction of the biliary tract.^{1,10,11} Chronic hemolysis leads to elevated bilirubin levels (mainly unconjugated), elevated plasma aspartate transaminase (AST) and plasma alanine transaminase (ALT), and altered liver function test results.^{1,10} Among the other frequently diagnosed complications, liver infarction has been found in as many as 34% of patients, acute sickle hepatic crisis in 10% of patients presenting with pain crisis, gallstones in 58% of patients, and cholelithiasis in 26%–58% of SCD homozygous patients.^{1,10} Intrahepatic cholestasis is a severe and possibly fatal complication of hepatic crisis and, importantly, liver cirrhosis has been reported to occur in ~18% of patients and leads to death in ~11% of those cases.¹ SCD sufferers also very frequently experience musculoskeletal symptoms, such as bone pain, which is a result of a vascular necrosis of the bones (osteonecrosis).^{12,13} The bone necrosis is believed to be caused by repeated vaso-occlusion, reduced blood flow to the bone tissue, and a resulting death of the tissue.^{12,13}

The laboratorial tests most frequently showed elevated (unconjugated) bilirubin levels, which correlated with lactate dehydrogenase levels, suggesting that hemolysis, and not liver disease, was the cause of hyperbilirubinemia.¹ Investigations regarding the concentrations of different Hb types have tended to indicate a lack of typical adult Hb type A (HbA), >90% concentration of Hb type S (HbS), and <10% concentration of fetal Hb (HbF) type F.^{8,14} The HbF type is frequently elevated in the sickle cell sufferers compared to the general population and has been shown to have protective properties, with patients exhibiting milder disease symptoms.¹⁴ The incidence of glucose-6-phosphate dehydrogenase (G6PD) deficiency in sickle cell patients is not different to that reported in the general population but, if present, has more profound negative effects in sickle cell patients than in the normal population.^{15,16} Other laboratorial tests in sickle cell patients have shown elevated platelet

and white blood cell (WBC) count, and increased platelet hyperactivity.^{5,17,18}

Due to the many comorbidities and complications of the disease, SCD patients undergo surgery more often and at an earlier age than members of the general population, which also puts them at an increased risk of further life-threatening or chronic complications.³ The most frequent procedures performed on these patients are cholecystectomies, splenectomies, and total hip replacement.^{3,19,20}

The specific aim of this study was to investigate the frequency and pattern of hepatobiliary abnormalities in SCD patients from Bahrain.

Methods

A prospective analysis of sickle cell anemia patients admitted to Salmaniya Medical Complex, Bahrain, between September 2013 and December 2014 was conducted in order to study the incidence of hepatobiliary abnormalities. Demographic information, including age, gender, nationality, weight, height, body mass index, vaccination history, smoking and alcohol status, age at the time of diagnosis, duration of disease, presence of other comorbidities, and family history of SCD, was collected. During the course of patients' admission, details including number of admissions, outcomes of hospitalization, and symptoms – with specific focus on bone and abdominal pain – were also recorded.

The diagnosis of SCD was established with a positive sickling test result, where the trait was identified by Hb electrophoresis. Hb capillary electrophoresis was conducted using a mini capillary instrument (Minicap; Sebia Inc., Norcross, GA, USA). Briefly, the sickling test was carried out by adding a drop of EDTA blood to five drops of freshly prepared reducing agent (2:3 sodium dithionate and disodium hydrogen phosphate). The slide was examined microscopically under a cover slip. Immediate sickling of erythrocytes occurs in positive cases.

Liver function tests included assessments of bilirubin, albumin, ALT, AST, and alkaline phosphatase (ALP). Prothrombin time was calculated, and results were expressed as an international normalized ratio (INR). Full blood count tests (Hb, WBC, and platelets) were performed using an automated blood counter, and patients were also tested for G6PD deficiency, hepatitis B surface antigen (HbsAg), and hepatitis C antibodies (anti-HCV). Confirmation of hepatitis B or C virus infections was done by polymerase chain reaction for all the patients with positive preliminary test results.

All patients were subjected to abdominal ultrasonographic examination in order to collect data on the status of the gall bladder, bile ducts, liver, and spleen. Further, the patients

were subjected to endoscopic retrograde cholangiopancreatography (ERCP) with or without sphincterotomy to obtain data on bile duct stones, biliary leak, or biliary strictures (benign or malignant); colectomy (open or laparoscopic) to obtain data on gall stones; and splenectomy for other reasons, such as acute splenic sequestration crisis, hypersplenism, massive splenic infarction, and splenic abscess.

Data are presented as mean \pm standard deviation for continuous variables and as percentages for categorical variables. As this was a prospective analysis, informed consent was obtained from all patients. The institutional ethics board of Salmaniya Medical Complex approved the study protocol.

Results

The average age of patients in the cohort was 31 years, with the youngest patient being 18 years old and the oldest 57 years. Females represented 64% (N=99) of the total sample. The average length of hospital stay varied from 1 to 119 days, and the number of admissions was similarly spread out, from as little as 2 to 259. The majority (95%) of patients presented with sickle cell (SS) Hb, 80% presented with bone pain, and all (100%) were diagnosed with bone crisis (Table 1).

Liver function and other laboratorial tests

The hematological tests revealed that 88% of patients had Hb levels below the normal range (<12.0 g/dL), with a mean level of 9.3 in the cohort (range 5.7–13 g/dL). The mean level of HbS was 73 g/dL. The patients in the cohort had raised

HbF, with an average level of 16 g/dL (range 1.1–75 g/dL), and HbA with an average of 4 g/dL (range 0–56 g/dL). HbS was identified in 79% of patients (range 22%–99%), HbF in 17% (range 1%–51%), and HbA in 4% (range 0%–61%). The analysis of bilirubin levels showed that only 9% (N=14) of the cohort had bilirubin levels within the normal range, with an average bilirubin level of 33 μ mol/L in the cohort, which is above the normal range (5–21 μ mol/L). The albumin levels in the cohort were also altered, with 20% (N=31) of the cohort having albumin levels below the normal range (<35 g/L). Other hematological test results also showed that 50% (N=77) of the patients had elevated WBC ($>9.6 \times 10^9/L$), 29% (N=45) had below normal platelet count, and 15% (N=23) had above the normal platelet count range of 150–400 ($\times 10^9/L$). The majority of patients (86%) did not have G6PD deficiency. However, 73% (N=112) had elevated ALT (≥ 33 U/L), 19% (N=30) elevated ALP (>136 U/L), and 60% (N=93) elevated GGT (>55 U/L). All the 154 patients in the cohort were negative for hepatitis B, but 14 patients (9%) were positive for hepatitis C (Table 2).

Ultrasound scanning (US) was performed in 42% (N=65) of cases. Normal US results were obtained for 22% (N=14) of patients. Hepatomegaly was the most common finding of the US, with 15 cases being diagnosed (23%) and hepatosplenomegaly was the second most common condition observed (20%), followed by cholelithiasis (15%), gallbladder sludge (15%), and splenomegaly (12%) (Table 3, Figure 1).

ERCP was performed in 12 cases (8%), and all of the patients who had ERCP exam underwent a sphincterotomy (N=12). The most common indication for a patient to be referred to ERCP was dilated bile ducts (67%), and the results of the procedure showed that seven of the patients had dilated bile ducts without stones (58%) (Table 3).

Laparoscopic cholecystectomy surgery was performed in fourteen (9%) cases and splenectomy in three cases (2%). The majority of the patients in the cohort did not receive any treatment (88%), and those who did (N=17) received blood transfusion with an average of two packed red blood cells units or deferoxamine (N=1) (Table 3).

Discussion

This study prospectively reviewed 154 charts of patients with SCD. The data showed that 95% of the patients in the cohort had homozygous sickle cell (SS) Hb type, and all the 154 patients were diagnosed with bone crisis, which presented as bone pain in 80% of cases. Musculoskeletal complications are among the most common complications in sickle cell patients.^{12,13} These are severe and have potentially devastating

Table 1 Diagnostic tests and procedures performed

Demographic data	Values
Number of patients	154
Age, years (mean, min–max)	31 (18–57)
Females (N, %)	99 (64%)
Males (N, %)	55 (36%)
Length of hospital stay, days (mean, min–max)	11 (1–119)
Number of admissions (mean, min–max)	50 (2–259)
Hospitalization outcome – alive (N, %)	152 (99%)
Clinical presentation (hemoglobin structure)	S-thal (7, 5%) SS (147, 95%)
Other comorbidities (N)	Asthma (1) Diabetes (1) Diabetes and dyslipidemia (1) Hypertension and cardiomyopathy (2)
Symptoms (N, %)	Bone pain (123, 80%) Abdominal pain (1, 1%)
Diagnosis (N, %)	Bone crisis (154, 100%)

Abbreviations: S-thal, hemoglobin S/thalassemia; SS, hemoglobin S – sickle cell.

Table 2 Hematological and biochemical profiles of the study cohort

Biochemical tests	Results	Normal range	Unit
Hemoglobin (Hb) (mean, min–max)	9.3 (5.7–13)	12.0–14.5	g/dL
HbS level (mean, min–max)	73 (30–94)	N/A	g/dL
HbF level (mean, min–max)	16 (1.1–75)	N/A	g/dL
HbA level (mean, min–max)	4 (0–56)	N/A	g/dL
Bilirubin level (mean, min–max)	33 (6–211)	5–21	μmol/L
Direct bilirubin (mean, min–max)	10 (2–116)	N/A	μmol/L
Indirect bilirubin (mean, min–max)	25 (5–116)	N/A	μmol/L
Albumin (mean, min–max)	38 (21–48)	35–52	g/L
WBC (mean, min–max)	10 (3.6–22)	3.6–9.6	×10 ⁹ /L
Platelet (mean, min–max)	250 (65–653)	150–400	×10 ⁹ /L
G6PD deficiency	Yes (14, 9%) No (133, 86%)	N/A N/A	N/A N/A

Hepatitis B (HbsAg) (N, %)	Negative (154, 100%)	N/A	N/A
Hepatitis B core (anti-HBc) (N, %)	No (154, 100%)	N/A	N/A
Hepatitis C (anti-HCV) (N, %)	Positive (14, 9%) Negative (140, 91%)	N/A N/A	N/A N/A

Abbreviations: WBC, white blood cell; G6PD, glucose-6-phosphate dehydrogenase; ALT, alanine aminotransferase; ALP, alanine phosphatase; GGT, γ-glutamyltransferase; HbS, hemoglobin type S; HbA, adult hemoglobin type A; HbF, fetal hemoglobin type F; HbsAg, hepatitis B surface antigen; N/A, not applicable.

Table 3 Diagnostic tests and procedures performed

Procedures	Results
Abdominal US (N, %)	Yes (65, 42%) No (89, 58%)
ERCP (N, %)	Yes (12, 8%) No (142, 92%)
ERCP indication (N, %)	Dilated bile ducts (8, 67%) Dilated bile ducts and stones (3, 25%) Cholestatic jaundice (1, 8%)
ERCP results (N, %)	Dilated bile ducts without stones (7, 58%) Dilated bile ducts with stones (4, 33%) Normal (1, 8%)
Laparoscopic cholecystectomy surgery (N, %)	Yes (14, 9%) No (140, 91%)
Sphincterotomy (N, %)	Yes (12, 8%)
Splenectomy (N, %)	3 (2%)
Treatment (N, %)	Blood transfusion (17, 11%) Deferoxamine (1, 1%) None (136, 88%)
Number of PRBC units (mean, min–max)	2 (1–2)

Abbreviations: US, ultrasound scanning; ERCP, endoscopic retrograde cholangiopancreatography; PRBC, packed red blood cells.

effects on patients' health and quality of life; yet there is no standardized treatment currently available.¹³ Of the various treatment management options, total arthroplasty is the most effective.¹²

The vast majority (88%) of patients had Hb levels below the normal range. The concentration of HbA was below the normal range but slightly higher (at 4%) than that reported

earlier for sickle cell patients (~0%).⁸ Similarly, the concentration of the protective HbF in this cohort was higher than that reported in SCD patients of earlier studies (17% in this cohort versus <10% in earlier reports).¹⁴ The patients had increased bilirubin and albumin levels and WBC count, as had been established in the earlier studies.^{1,5,17,18} The liver function tests also showed typically abnormal results, with ALT and GGT outside the normal ranges. On a positive note, the incidence of hepatitis B and C in this cohort was very low, at 0% and 9%, respectively. Previous studies have reported prevalence rates of ~1.8% and 12.5%, respectively, for hepatitis B and C infections among SCD patients.²¹ The reasons for this discrepancy might include better and more efficacious screening of the transfused blood, increased vaccination rates, and the lower number of transfusions received by the patients in this cohort.

SCD patients tend to undergo numerous hospital visits, surgeries, and other clinical procedures compared to the normal population.³ A similar trend was identified in this cohort. The surgery types and diagnostic procedures most frequently performed in this cohort were ultrasound of the abdomen, ERCP, cholecystectomy, sphincterotomy, and splenectomy. Contrary to the previously published data reporting a large number of blood transfusions among SCD patients, only 17 transfusions were performed in this cohort.¹⁰ The reasons for the difference include a relatively low sickle cell Hb concentration and a lack of splenic sequestration, aplasia, or vaso-occlusive events.²²

Figure 1 Abdomen ultrasound scanning results: a pie chart showing the types and frequency of pathological findings.

Abbreviations: GB, gallbladder; infarct, infarction; 5IHD, type 5 intrahepatic bile duct.

The findings of the abdomen ultrasound procedure were similar to those reported in earlier studies, with only 14 of the 65 performed ultrasounds being normal.²³ Hepatomegaly, splenomegaly, and cholelithiasis were the most common ultrasound findings. These findings are also similar to those reported in earlier studies.²³

Conclusion

This cohort differed from those in previously published reports with regard to the lower number of blood transfusions, lower prevalence of hepatitis B and C infections, and enhanced concentrations of HbF and HbA. As expected, the SCD had profound negative effects on multiple organs, with a particularly large number of complications related to the hepatobiliary system, reflected in the number of abdomen ultrasound scan findings, poor liver function test results, and high bilirubin levels.
