Abstract: Ixazomib is the first oral proteasome inhibitor to be approved, in combination with lenalidomide and dexamethasone, for the treatment of patients with multiple myeloma who have received at least one prior therapy. Approval was on the basis of results from the phase 3, double-blind, placebo-controlled TOURMALINE-MM1 study, which demonstrated a 35% improvement in progression-free survival with the all-oral combination of ixazomib plus lenalidomide–dexamethasone versus lenalidomide–dexamethasone alone (median: 20.6 vs 14.7 months; hazard ratio: 0.74, \(p=0.012\); median follow-up 14.7 months). The addition of ixazomib to the lenalidomide–dexamethasone regimen was associated with limited additional toxicity and had no adverse impact on patient-reported quality of life. Common grade \(\geq 3\) adverse events with ixazomib include gastrointestinal adverse events, rash, and thrombocytopenia. Here, we review the efficacy, safety, pharmacokinetics, and patient-reported quality of life data seen with ixazomib, and discuss the role of this oral agent in the treatment of patients with relapsed/refractory multiple myeloma, including in patients with high-risk cytogenetic abnormalities and those with multiple prior therapies.

Keywords: ixazomib, multiple myeloma, proteasome inhibitor, clinical, efficacy, tolerability, pharmacokinetics

Introduction

Multiple myeloma (MM) is a malignant plasma cell disorder characterized by the uncontrolled proliferation of monoclonal plasma cells in the bone marrow.1,2 It is the second most common hematologic malignancy and accounts for \(\sim 16.6\%\) of all hematologic malignancies in the US,1 with an estimated worldwide 5-year prevalence in 2012 of 229,468 people.4 The risk of developing MM increases with age, and the median age at diagnosis is 69 years.1

The treatment of MM has advanced over the past 15 years following the introduction of the immunomodulatory drugs thalidomide, lenalidomide, and pomalidomide, and the proteasome inhibitors bortezomib and, more recently, carfilzomib5 and ixazomib.6 Median overall survival (OS) has improved from 4.6 years for patients diagnosed between 2001 and 2005 to 6.1 years for patients diagnosed between 2006 and 2010.7

Despite these advances, MM is a complex and incurable progressive disease characterized by multiple relapses, largely due to the persistence of residual disease, and the need for multiple lines of therapy.8–10 Based on real-world and claims analyses, \(\sim 48\%–66\%\) of patients are estimated to progress following first-line therapy and require subsequent lines of treatment, with other patients not reported as receiving
subsequent therapy, possibly due to death or censoring prior to subsequent treatment, or loss to follow-up.\textsuperscript{11–13} Furthermore, similar analyses have indicated that \textasciitilde21\%–43\% of patients are estimated to require third-line treatment and beyond.\textsuperscript{11–13} After each remission, MM typically recurs with a more aggressive disease course, resulting in shorter duration of disease response with each successive line of therapy and, eventually, treatment-refractory disease.\textsuperscript{14}

Consequently, there has been a high unmet clinical need to expand the active treatment options, prolong therapy, and further improve outcomes for patients with relapsed/refractory MM (RRMM). There are also several “poor prognosis” groups of patients with MM for whom outcomes with current standards of care are poorer compared with those in the general MM patient population; these include patients with the high-risk cytogenetic abnormalities del(17p), t(4;14), and t(14;16)\textsuperscript{15–18}; elderly patients (aged \textgtr75 years)\textsuperscript{19,20}; patients with renal impairment\textsuperscript{21}; and patients with high disease burden.\textsuperscript{2,22}

**Current and emerging treatment options in MM**

**Current treatment options for patients with MM**

In the era of novel therapies, the immunomodulatory drugs lenalidomide and thalidomide, and the proteasome inhibitor bortezomib are the backbone of therapy for MM, often administered in two- or three-drug combinations with corticosteroids (such as dexamethasone or prednisone) and alkylating agents (such as melphalan or cyclophosphamide). These agents are used at all stages of the disease: as induction therapy prior to autologous stem cell transplant (ASCT), as initial therapy for newly diagnosed patients ineligible for ASCT, and as subsequent lines of therapy following relapse of the disease. Following the widespread use of immunomodulatory drugs and proteasome inhibitors, there is increasing evidence to support the use of the newer immunomodulatory drugs and proteasome inhibitors pomalidomide, carfilzomib, and ixazomib in patients with relapsed/refractory disease.\textsuperscript{6,14}

While investigation into the optimal combinations and therapeutic strategies continues, results support the benefits of triplet versus doublet regimens.\textsuperscript{6,23–31} Several studies have also demonstrated that a triplet regimen including both an immunomodulatory drug and a proteasome inhibitor, such as bortezomib, carfilzomib, or ixazomib in combination with lenalidomide–dexamethasone (Rd), is particularly effective at inducing rapid and deep responses, leading to improved progression-free survival (PFS) and, in the case of bortezomib-Rd, OS.\textsuperscript{6,23–25,29,32}

Long-term treatment is now emerging as a standard-of-care with the goals of continuous disease suppression, deepening responses, and prolonging survival. The benefits of continuous MM therapy have been demonstrated following ASCT or following an induction regimen, with sustainable, long-term maintenance treatment being associated with better OS versus fixed-term treatment.\textsuperscript{33–35} Long-term treatment appears particularly important for patients with high-risk cytogenetic abnormalities,\textsuperscript{36} for whom there are few effective treatment options. However, long-term treatment with current triplet regimens, particularly those including the proteasome inhibitors bortezomib or carfilzomib, is difficult to achieve as they have been associated with a substantial patient burden in terms of both treatment-related toxicities,\textsuperscript{14} such as peripheral neuropathy (PN),\textsuperscript{37} cardiovascular\textsuperscript{14} and renal\textsuperscript{38} toxicities, and the need for frequent clinic visits and repeat injections,\textsuperscript{39} all of which can have an adverse impact on duration of therapy. Real-world data from one retrospective cohort study showed median duration of second-line treatment to be just 6.9 months for an intravenously administered PI,\textsuperscript{40} which is in contrast to the \textasciitilde20 months reported in a recent phase 3 trial in patients with RRMM,\textsuperscript{29} highlighting the need for new treatment strategies to enable patients to achieve sustainable and long-term benefit from their MM therapy.

The aim of achieving long-term treatment has also focused attention on improved patient quality of life (QoL), particularly with regard to the tolerability and convenience of the treatment regimen.\textsuperscript{41} Consequently, effective, sustainable therapies associated with manageable toxicities may have an important role in the treatment of MM, with the potential ability to enable long-term therapy.

**Emerging therapeutic options for RRMM**

Adding to the treatment armamentarium for patients with RRMM, several agents have recently been approved by the US Food and Drug Administration (FDA) for the treatment of RRMM. These include the histone deacetylase inhibitor panobinostat, the monoclonal antibodies elotuzumab and daratumumab, and the oral proteasome inhibitor ixazomib, many of which have been approved as components of triplet regimens including proteasome inhibitors or immunomodulatory drugs. For example, the histone deacetylase inhibitor panobinostat has been approved in combination with bortezomib and dexamethasone after showing longer PFS when
compared with bortezomib plus dexamethasone. Similarly, the monoclonal antibodies elotuzumab and daratumumab have demonstrated encouraging PFS when administered in combination with the proteasome inhibitor bortezomib or immunomodulatory drug lenalidomide, plus dexamethasone, with daratumumab approved as a single agent and showing particular promise in triplet regimens.

The oral proteasome inhibitor ixazomib has been approved in more than 40 countries, including the United States and the European Union, for the treatment of MM patients, in combination with Rd, who have received at least one prior therapy. This approval was based on data from the phase 3 randomized, double-blind, placebo-controlled TOURMALINE-MM1 trial in 722 patients with relapsed/refractory MM, which demonstrated a 35% improvement in PFS, and a generally manageable toxicity profile. Here, we review the role of ixazomib in the management of relapsed/refractory MM, focusing on the pharmacokinetics (PK), efficacy, and safety of this oral proteasome inhibitor.

Clinical pharmacology of ixazomib
Ixazomib is a reversible proteasome inhibitor that preferentially binds and inhibits the 20S proteasome. Ixazomib is administered as the citrate ester prodrug (ixazomib citrate), which undergoes rapid and complete hydrolysis to the bioactive agent ixazomib under physiological conditions, which undergoes rapid and complete hydrolysis to the bioactive agent ixazomib under physiological conditions. The first oral proteasome inhibitor to be approved for the treatment of MM, prior to approval, the clinical development of ixazomib included a comprehensive clinical pharmacology characterization, based on phase 1 study data and other dedicated studies, which helped to understand the PK properties of ixazomib and inform its posology.

Pharmacokinetics
Early-phase studies investigated weekly and twice-weekly dosing schedules of single-agent ixazomib (weekly, days 1, 8, and 15 of 28-day cycles; twice-weekly, days 1, 4, 8, and 11 of 21-day cycles). Results demonstrated that, with both dosing schedules, ixazomib was rapidly absorbed (the median time to maximum plasma concentration was 1 hour) and had a long terminal half-life of 9.5 days, supporting the use of both ixazomib schedules. Data from these early-phase studies also demonstrated the dose-proportional nature of ixazomib plasma exposure.

Ixazomib is highly plasma protein bound (99%) and distributes into red blood cells with a blood-to-plasma ratio of 10 (Merlini et al, unpublished data). Metabolism by multiple CYP enzymes and non-CYP proteins is expected to be the major clearance mechanism for ixazomib. Preclinical data have shown that, at clinically relevant ixazomib concentrations, no specific CYP isozyme predominantly contributes to ixazomib metabolism and non-CYP enzymes also contribute to overall metabolism. However, at concentrations exceeding those observed clinically (≥90-fold), ixazomib was metabolized in vitro by multiple CYPs, with CYP3A contributing to the greatest extent (42%).

Cardiac electrophysiology
As cardiac events have been associated with other proteasome inhibitors, part of the early characterization of ixazomib was to evaluate any effect of ixazomib on cardiac parameters. Within this cardiac effect characterization, an innovative concentration-QTc analysis integrating data from four phase 1 studies of single-agent ixazomib (N=245) demonstrated that ixazomib has no clinically meaningful effects on QTc interval or heart rate.

Dose selection and posology
Phase 1 studies of single-agent ixazomib demonstrated the maximum tolerated dose (MTD) of ixazomib to be 2.97 mg/m² for the weekly schedule and 2.0 mg/m² for the twice-weekly schedule. Similarly, a MTD of 2.97 mg/m² was also demonstrated for weekly ixazomib in combination with Rd, with a recommended phase 2 dose of 2.23 mg/m².

In contrast to the body surface area-based dosing used for bortezomib and carfilzomib, ixazomib administration involves a simple, fixed-dosing approach. The feasibility of this was demonstrated in a population PK analysis using pooled data from four phase 1 studies. This analysis indicated that ixazomib has high oral bioavailability and that body size does not impact ixazomib exposure, demonstrating that fixed rather than body surface area-based ixazomib dosing is appropriate. The MTD of 2.97 mg/m² and recommended phase 2 dose of 2.23 mg/m² ixazomib reported in the phase 1 study of weekly ixazomib plus Rd equate to fixed doses of 5.5 mg and 4.0 mg, respectively. Simplifying ixazomib administration, a fixed ixazomib dose of 4.0 mg, in combination with Rd, is used in current phase 3 studies.

As the PK and safety profiles of a drug can vary by ethnicity, following the phase 1 studies in Western patients, the PK of ixazomib was assessed in East Asian patients. Ixazomib exposures on day 1, cycle 1 were similar to those seen in Western patients. Although the exposure on day 15, after multiple dosing, was ~30% higher in East Asian patients, this increased exposure at the 4.0 mg dose was...
Clinical efficacy in patients with MM

Single-agent ixazomib

The clinical efficacy of single-agent ixazomib in patients with relapsed/refractory MM was demonstrated in two phase 1 studies in heavily pretreated patients, including those with prior bortezomib and prior lenalidomide exposure (Table 1). Sixty patients were enrolled to each study and received single-agent ixazomib on a weekly (days 1, 8, and 15 of 28-day cycles) or twice-weekly (days 1, 4, 8, and 11 of 21-day cycles) schedule. Antimyeloma activity was demonstrated with both weekly and twice-weekly single-agent regimens (Table 1); of note, responses were seen in patients with relapsed and refractory MM who had previously received both bortezomib and lenalidomide. These preliminary data indicated that responses were rapid and durable, with time to first response of 1.6–4.4 months, and duration of disease control of >28 months reported.49

The efficacy of single-agent ixazomib has also been demonstrated by the results from a phase 2 Mayo Clinic study (Table 1). In the first phase of this study, 33 patients with RRMM and who had received a median of 2 prior therapies (72% were bortezomib-naïve) received weekly ixazomib 5.5 mg, with additional dexamethasone for insufficient response.64 A second phase of this trial assessed the efficacy and tolerability of two doses of weekly ixazomib (4.0 mg and 5.5 mg) plus dexamethasone in heavily pretreated patients who had received a median of 4 prior therapies (range: 2–6); 90% of patients had received prior immunomodulatory drugs and 29% had received prior bortezomib. Overall response rates were 31% with ixazomib 4.0 mg and 51% with ixazomib 5.5 mg, indicating the efficacy in these heavily pretreated patients.65

Ixazomib in combination with Rd

Ixazomib is approved in combination with Rd in RRMM patients who have received at least one prior therapy, based on results from the phase 3 placebo-controlled, double-blind TOURMALINE-MM1 study.6 The rationale for this phase 3 study and the feasibility of the all-oral ixazomib–Rd triplet combination was demonstrated in two phase 1/2 studies in the newly diagnosed setting. These two studies assessed weekly ixazomib plus Rd (4 mg ixazomib on days 1, 8, and 15 of 28-day cycles, plus Rd) and twice-weekly ixazomib plus Rd

Abbreviations: Cd, cyclophosphamide-dexamethasone; CR, complete response; dex, dexamethasone; EFS, event-free survival; mo(s), month(s); HR, hazard ratio; MM, multiple myeloma; MP, melphalan-prednisone; MR, minimal response; MTD, maximum tolerated dose; nCR, near complete response; NR, not reported; ORR, overall response rate; OS, overall survival; PR, partial response; pts, patients; Rd, lenalidomide-dexamethasone; sCR, stringent CR; VGPR, very good partial response.
(3 mg ixazomib on days 1, 4, 8, and 11 of 21-day cycles, plus Rd) in patients with newly diagnosed MM, including those eligible for ASCT.47,49,60 In both studies, patients received a fixed number of induction cycles of the ixazomib–Rd regimen followed by maintenance therapy with single-agent ixazomib on the same schedule. Encouraging efficacy was reported with both schedules (Table 1), with 62% and 76% of patients achieving very good partial response (VGPR) with weekly and twice-weekly ixazomib plus Rd.47,49,60 These data indicate the quality of response attained and suggest there may be a clinical role for weekly and twice-weekly ixazomib dosing regimens. Importantly, in the context of long-term treatment, results from the phase 1/2 study of weekly ixazomib plus Rd demonstrated the feasibility of extended treatment, with patients remaining on therapy for >4 years and demonstrating deepening responses with maintenance therapy.7,47

On the basis of these encouraging early-phase results, ixazomib–Rd versus placebo–Rd was assessed in the global phase 3, randomized, double-blind, placebo-controlled TOURMALINE-MM1 study. Uniquely in phase 3 studies of MM triplet regimens, the all-orphan administration of the ixazomib–Rd regimen enabled a placebo–controlled, double-blind study design, in which the independent review committee was blinded to both patient assignment and investigator response assessment, increasing the rigor and reliability of the study. The inclusion criteria were particularly broad to better represent the global MM patient population, including patients with mild-to-moderate renal impairment, primary refractory patients, patients with free light chain-only disease, and patients from East Asia.6

A total of 722 patients were randomized to receive ixazomib 4 mg weekly versus matching placebo plus lenalidomide and dexamethasone, until disease progression or unacceptable toxicity.6 After a median follow-up of ~15 months, there was a 35% improvement in the primary endpoint PFS with ixazomib–Rd vs placebo–Rd (hazard ratio [HR], 0.74, \( p=0.01 \)), equating to a clinically meaningful ~6 month benefit in median PFS (median PFS 20.6 months vs 14.7 months; Table 1, Figure 1A).6 Differences in study designs, methodologies, and patient populations limit cross-trial comparisons; however, the relative benefit with ixazomib–Rd versus placebo–Rd appeared consistent with HRs reported versus Rd for other proteasome inhibitor–Rd combinations.29

Overall response rates and ≥VGPR rates were 78.3% versus 71.5% (\( p=0.04 \)) and 48% versus 39% (\( p=0.01 \)) with ixazomib–Rd versus placebo–Rd (Table 1). Responses were rapid and durable, with a median time to response of 1.1 months versus 1.9 months and a median duration of 20.5 months versus 15.0 months in the ixazomib–Rd and placebo–Rd arms, respectively. Importantly in the context of long-term treatment, deepening responses were noted with increasing treatment duration,6 as seen in the earlier phase 1/2 study.47 OS data were not yet mature, and longer follow-up data are needed.

A separate regional expansion of the global TOURMALINE-MM1 study was conducted in China. The results of this China continuation study showed a consistent PFS benefit with ixazomib–Rd versus placebo–Rd (HR for PFS 0.6, \( p=0.035 \)) and a consistent improvement in overall response rates (\( p=0.007 \)), supporting the overall treatment benefit of the ixazomib–Rd regimen.66 Consistent with the global study, there was limited additional toxicity with ixazomib–Rd versus placebo–Rd.66

The ixazomib–Rd combination is also being assessed versus placebo–Rd in the newly diagnosed setting in the phase 3, double-blind, placebo-controlled TOURMALINE-MM2 study (NCT01850524). The study is ongoing, but recruitment is now complete.

**Efficacy of ixazomib in specific patient populations**

The clinically meaningful PFS benefit with ixazomib–Rd versus placebo–Rd in the TOURMALINE-MM1 study was seen across patient subgroups, including those with a poor prognosis such as those with high-risk cytogenetic abnormalities and multiple prior therapies (Figure 1B).

**Patients with high-risk cytogenetic abnormalities**

Patients with high-risk cytogenetic abnormalities have a particularly poor prognosis.15–18 The 2016 International Myeloma Working Group consensus paper recommends a triplet regimen including a proteasome inhibitor and an immunomodulatory drug for the treatment of patients with high-risk cytogenetic abnormalities.16,67 Further, patients with such poor prognosis should be treated until disease progression, recognizing the risk of rapid relapse in the absence of sustained exposure to chemotherapy.67 Although such regimens have shown improved outcomes vs previous standards of care in these patients, more needs to be done to close the gap vs patients with standard-risk cytogenetics.

In the 137 patients with the high-risk cytogenetic abnormalities del(17p), t(4;14), and/or t(14;16) in TOURMALINE-MM1, the HR for PFS was 0.543 (95% CI: 0.321, 0.918; \( p=0.021 \)), and there was more than a doubling in median PFS with ixazomib–Rd versus placebo–Rd (median PFS 21.4 vs 9.5 months).66 Of note in
The role of ixazomib in relapsed/refractory multiple myeloma

Figure 1 Kaplan–Meier analysis of PFS in the TOURMALINE-MM1 study on the intent-to-treat population (A) and by prespecified patient subgroups (B) (data from final statistical analysis for progression-free survival).

Abbreviations: CI, confidence interval; HR, hazard ratio; mo, month; NE, not estimable; PFS, progression-free survival.
this particularly poor prognosis patient population, the median PFS with ixazomib–Rd was similar to that seen in patients with standard-risk cytogenetics (median PFS with ixazomib–Rd, 21.4 months in high-risk patients vs 20.6 months in standard-risk patients).

The PFS benefit with ixazomib–Rd versus placebo–Rd was consistent according to the presence or absence of each cytogenetic abnormality, all of which have been shown to be independent poor prognostic markers in MM. Of note, the median PFS in the ixazomib group was 21.4 months in patients with del(17p), which appeared similar to the median of 20.6 months in the standard-risk patients.

There is currently no agreed minimum percentage of plasma cells carrying del(17p) for defining the presence of this abnormality and for conferring poor prognosis; different studies have used different values, ranging from the presence of a single cell to a cut-off threshold of 60% of cells. In the absence of an agreed standard, the protocol-specified cut-off in TOURMALINE-MM1 was 5%, based on the false-positive rate of the fluorescence in situ hybridization probe used; however, a consistent PFS benefit was seen in post hoc analyses using cut-offs of 20% and 60% of cells, with HRs ranging from 0.490 to 0.611.

Patients with prior exposure to proteasome inhibitors/immunomodulatory drugs

Given the widespread use of immunomodulatory drugs and proteasome inhibitors as front-line therapy, it is important for an RRMM regimen to demonstrate efficacy in patients with prior exposure to these agents. The TOURMALINE-MM1 study included patients with prior exposure to proteasome inhibitors and immunomodulatory drugs, although patients refractory to proteasome inhibitors or lenalidomide were not eligible (patients refractory to thalidomide were included; refractoriness was defined as disease progression on treatment or within 60 days after last dose of therapy). Of 722 patients, 69% had prior proteasome inhibitor therapy and 55% had prior thalidomide/lenalidomide therapy (23% were refractory to thalidomide). Results demonstrated a consistent efficacy benefit in terms of prolonged PFS with ixazomib–Rd versus placebo–Rd regardless of prior exposure to proteasome inhibitor or immunomodulatory drug therapy (HRs of 0.70–0.75 for proteasome inhibitor or immunomodulatory drug-exposed/-naïve patients; Figure 1B). This consistent benefit with ixazomib–Rd was also seen in patients who were refractory to their last prior therapy (HR 0.71, vs placebo-Rd).

Patients with multiple prior therapies

Long-term outcomes, including PFS and OS, are known to worsen with increasing numbers of prior therapies, possibly due to the development of treatment-resistant clones and also increased rates of comorbidities and complications. Effective therapies are therefore needed for this patient population. In the TOURMALINE-MM1 study, ixazomib–Rd was associated with a consistent PFS benefit versus placebo–Rd in patients with 1, 2, or 3 prior therapies, with a notable PFS benefit in patients with multiple prior therapies (Figure 1B). Of note, the benefit with ixazomib–Rd versus placebo–Rd extended to patients who were refractory to their last prior therapy and to those who were relapsed and refractory (Figure 1B).

Ixazomib in other combination regimens

Reflecting combinations also studied during the clinical development of the first-in-class proteasome inhibitor bortezomib, preliminary efficacy data have been reported for ixazomib in combination with cyclophosphamide–dexamethasone, melphalan–prednisone, panobinostat–dexamethasone, and pomalidomide–dexamethasone, supporting the suitability of ixazomib as a partner agent in combination regimens.

Ixazomib is being investigated in combination with cyclophosphamide–dexamethasone, to give another all-oral triplet regimen. Weekly ixazomib (4 mg) plus cyclophosphamide (300 mg or 400 mg weekly) and dexamethasone is being investigated in patients with RRMM and in those with newly diagnosed MM, transplant-ineligible MM in a phase 2 study (NCT02046070). The first report from the study has shown preliminary efficacy in patients with newly diagnosed MM, with an overall response rate of 71% after a median of 9 treatment cycles (78% vs 65% in the ICd-300 and ICd-400 arms, respectively), including a ≥VGPR rate of 26% (28% vs 21% with ICd-300 and ICd-400, respectively; Table 1). As seen with the ixazomib–Rd regimen, responses appeared to deepen over time.

Ixazomib is also under investigation in combination with panobinostat and dexamethasone. Although only including 11 patients, preliminary data from a phase 1 study of ixazomib plus panobinostat–dexamethasone (NCT02057640) indicated some activity in heavily pretreated RRMM patients who had received a median of 5 prior therapies (range, 2–10) (Table 1).

Building on the results seen with ixazomib plus lenalidomide and dexamethasone, initial results from two phase 1/2 studies have indicated encouraging preliminary efficacy with
ixazomib in combination with pomalidomide and dexamethasone, including in patients refractory to prior bortezomib or lenalidomide therapy. The phase 2 portions of both studies are ongoing, and updated data are expected.

Safety and tolerability

With the addition of the phase 3 TOURMALINE-MM1 data to the early-phase data reported previously, the generally manageable toxicity profile of ixazomib is becoming clear. Commonly reported adverse events (AEs) across studies of ixazomib, both as a single-agent and in combination regimens, included gastrointestinal AEs (diarrhea, constipation, nausea, vomiting), rash, and thrombocytopenia (Table 2), many of which appeared primarily to be low-grade. Encouragingly for the development of combination regimens, the addition of ixazomib to the Rd regimen was associated with limited additional toxicity, with similar rates of AEs (98% vs 99%), serious AEs (47% vs 49%) and deaths during the study period (4% vs 6%), and only a small increase in the rates of grade ≥3 AEs (74% vs 69%) with ixazomib-Rd vs placebo-Rd. Discontinuation of treatment due to AEs was similar on the two regimens, allowing for long-term use of this regimen.

Key AEs seen in ixazomib studies

Thrombocytopenia

Thrombocytopenia is an overlapping toxicity seen with ixazomib and lenalidomide, and has been seen in early-phase trials of single-agent ixazomib and ixazomib in combination with Rd (Table 2).

Consistent with previous results with bortezomib, and results from the phase 1/2 study of ixazomib–Rd, there were transient and cyclical decreases in platelet count in both the ixazomib–Rd and placebo–Rd groups in TOURMALINE-MM1. Although the rate of grade 3/4 thrombocytopenia was higher with ixazomib–Rd versus placebo–Rd (12%/7% vs 5%/4%), most events appeared manageable with dose interruptions and reductions; there were few apparent clinical sequelae as the rates of serious AEs of thrombocytopenia (2%/5%), platelet transfusions (8% and 6%), study regimen discontinuation due to thrombocytopenia (1% in each group), and the occurrence of any-grade bleeding events (20% vs 19%) were similar in the two groups. Most thrombocytopenia events occurred within the first 3 cycles of therapy and there seemed to be no long-term cumulative toxicity.

In early-phase studies, the incidence of thrombocytopenia was similar with weekly and twice-weekly single-agent ixazomib (43% vs 42% overall, including 33% vs 37% grade ≥3), and with weekly and twice-weekly ixazomib in combination with Rd (grade ≥3 thrombocytopenia 8% vs 6%) (Table 2).

Gastrointestinal AEs

Consistent with results from early-phase studies of single-agent ixazomib and ixazomib–Rd, diarrhea was a common AE in the TOURMALINE-MM1 study (Table 2). However, also consistent with previous studies, most such events were of low grade and there were no apparent differences between the ixazomib–Rd and placebo–Rd groups in the incidence of potential complications of diarrhea such as hypokalemia, dehydration, weight loss, hyponatremia, and hypomagnesemia. The incidence of the first occurrence of diarrhea was highest during the first 3 months of treatment in both groups and generally declined over time. With ixazomib–Rd, the onset was predictable, primarily the day of or the day after ixazomib dosing. Antidiarrheal medications were used to manage diarrhea at the physician’s discretion, with loperamide being the most commonly prescribed medication.

Nausea and vomiting were also reported in early-phase studies of ixazomib. In TOURMALINE-MM1, nausea and vomiting were more common with ixazomib–Rd versus placebo–Rd, but were primarily seen within the first few months of treatment and were low-grade and manageable; 21% and 13% of patients in the ixazomib–Rd and placebo–Rd groups used antiemetics.

Rash

Rash was identified as a common AE in phase 1 studies of single-agent ixazomib and of ixazomib–Rd, with incidences of skin and subcutaneous tissue disorders (MedDRA System organ class) ranging from 22% to 55%, including 3%–17% grade ≥3 events (Table 2). Using the higher level term rash, eruptions, and exanthems not elsewhere classified, as reported in the US prescribing information, the incidences were 20% versus 13% for any-grade events, including 2% versus 2% for grade 3 events. Typical interventions included antihistamines or topical glucocorticoids, but the rash events tended to occur within the first few cycles and resolved without intervention in 21% of patients in the ixazomib–Rd group and 12% in the placebo–Rd group.

Peripheral neuropathy

PN is common with the first-in-class proteasome inhibitor bortezomib, particularly when administered intravenously rather than subcutaneously. Much lower incidences have

Notes: Number of response-evaluable patients/total number of treated patients.

Abbreviations: AE, adverse event; CD, cyclophosphamide–dexamethasone; dex, dexamethasone; mo(s), month(s); MM, multiple myeloma; MP, melphalan–prednisone; MTD, maximum tolerated dose; NR, not reported; PN, peripheral neuropathy; pts, patients; Rd, lenalidomide–dexamethasone; RRMM, relapsed and/or refractory multiple myeloma.
been reported with carfilzomib. Low incidences of PN were similarly reported in early-phase studies of ixazomib–Rd and single-agent ixazomib, and supported by the phase 3 TOURMALINE-MM1 study results (Table 2). There was a 5% difference in the incidence of PN between treatment arms in the double-blind, placebo-controlled TOURMALINE-MM1 study: 27% versus 22% in the ixazomib–Rd versus placebo–Rd arms, with no difference in grade 3 PN (2% in each arm). In the ixazomib–Rd and placebo–Rd arms, the incidence of PN was similar in bortezomib-exposed and bortezomib-naïve patients (25% vs 31% with ixazomib–Rd, and 21% vs 23% with placebo–Rd).

**Neutropenia**

Neutropenia increases the risk of bacterial and fungal infections and is commonly reported with MM therapy, including bortezomib and lenalidomide. Phase 1 studies of single-agent ixazomib reported incidences of grade ≥3 neutropenia of 18% and 17% with weekly and twice-weekly ixazomib (Table 2), possibly reflecting patient populations with low absolute neutrophil counts at baseline. However, similar rates of grade ≥3 neutropenia were seen in the ixazomib–Rd and placebo–Rd groups in the TOURMALINE-MM1 study (22% vs 24%, respectively), together with similar rates of granulocyte colony-stimulating factor use (21% vs 20%), suggesting similar rates of neutropenia with the addition of ixazomib to the Rd regimen. Neutropenia was reported most frequently within the first 3 cycles, with no cumulative effect seen across the study.

**Other AEs of clinical interest**

Consistent with the findings of the PK concentration-QTc analysis, there have been no safety concerns with respect to cardiac toxicity for ixazomib. In TOURMALINE-MM1, there were similar incidences of cardiac arrhythmia, heart failure, and myocardial infarction in the ixazomib–Rd and placebo–Rd arms (16% vs 15%, 4% in each arm, 1% vs 2%, respectively).

Similarly, there appear to be no safety concerns for ixazomib with respect to renal failure or thromboembolism. In TOURMALINE-MM1, the rates of any-grade renal failure (9% vs 11%) and any-grade thromboembolism (8% vs 11%) were similar with ixazomib–Rd and placebo–Rd.

**Patient-reported QoL**

With the increased focus on long-term treatment, patient-reported QoL is an increasingly important endpoint in MM clinical trials. Patient-reported QoL was a secondary endpoint of TOURMALINE-MM1 and was assessed using the EORTC QLQ-C30 and MY-20 questionnaires. Over a median follow-up of 23 months, the addition of ixazomib to the Rd regimen appeared to have no adverse impact on patient-reported QoL, with similar mean EORTC QLQ-C30 global scores and MY-20 side effect scores maintained during treatment in both the ixazomib–Rd and placebo–Rd arms, with significantly higher mean scores seen in the ixazomib–Rd vs placebo–Rd arm for the physical, emotional, and social scales, supporting the feasibility of long-term administration of the ixazomib–Rd regimen. These QoL data are notable given that TOURMALINE-MM1 was a double-blind, placebo-controlled study, and there can be a tendency to overestimate QoL and underestimate treatment burden in the active arms of open-label studies.

The sustainability of the ixazomib–Rd regimen was also highlighted by the high median relative dose intensity for ixazomib (97.4% for ixazomib vs 98.8% for placebo); median relative dose intensities for lenalidomide and dexamethasone were also similar between the two arms (93.8% vs 96.6% for lenalidomide, 92.2% vs 94.9% for dexamethasone).

**Ongoing phase 3 trials in MM**

In addition to the TOURMALINE-MM1 study, three other phase 3 studies of ixazomib in MM are ongoing (Table 3). In the TOURMALINE-MM2 study (NCT01850524), weekly ixazomib–Rd and placebo–Rd are being compared in newly diagnosed patients with MM who are not eligible for ASCT. As with TOURMALINE-MM1, the study incorporates a continuous therapy approach, with patients being treated until disease progression or unacceptable toxicity; after 18 cycles of initial treatment, dexamethasone will be stopped after 18 cycles of initial treatment, dexamethasone will be continued until disease progression or unacceptable toxicity.

---

The role of ixazomib in relapsed/refractory multiple myeloma...
discontinued and lenalidomide and ixazomib will be continued at a reduced dose until progression. The TOURMALINE-MM3 (NCT02181413) and TOURMALINE-MM4 (NCT02312258) studies are assessing ixazomib, versus placebo, as maintenance therapy. Patients with newly diagnosed MM who have had a response to induction therapy followed by ASCT are eligible for TOURMALINE-MM3, and NDMM patients who have had a response to induction therapy but have not undergone ASCT are eligible for TOURMALINE-MM4. In both studies, patients will receive ixazomib at a fixed dose of 3.0 mg for the first 4 cycles, which will then be increased to 4.0 mg if tolerability is acceptable, per the results of the exposure–safety–efficacy analyses.84

This comprehensive phase 3 program is complemented by a large investigator-initiated clinical study program (>70 ongoing investigator-initiated clinical studies), with MM cooperative groups throughout the world now assessing ixazomib in a clinical trial setting. Further, the open-label observation INSIGHT-MM trial (NCT02761187) will collect “real-world” clinical data on ixazomib outside of a clinical trial setting. This continued clinical research aims to further understand both the disease and the role of ixazomib in its treatment.

Conclusion
Proteasome inhibition is a backbone of MM treatment, and the oral proteasome inhibitor ixazomib is a promising MM treatment, demonstrating anti-myeloma activity and a generally well-tolerated and manageable toxicity profile, both as a single agent and in combination.

Data from the phase 3 TOURMALINE-MM1 study demonstrated that ixazomib adds another option to the RRMM treatment armamentarium, with a similar HR seen for ixazomib plus Rd versus Rd as seen in other studies of proteasome inhibitors plus Rd. Together with limited additional toxicity, and maintained patient-reported QoL, the oral administration of ixazomib may offer a simpler, less burdensome, and sustained proteasome inhibitor therapy. Particularly encouraging data have also been reported in patients with a poor prognosis, such as those with multiple prior lines of therapy and those with high-risk cytogenetic abnormalities. The efficacy in patients with high-risk cytogenetics is particularly notable, as these patients appear to need prolonged, sustained, active therapy with a proteasome inhibitor,36,67 all of which appears feasible with ixazomib.

Importantly in the era of triplet regimens, PK studies have also shown that ixazomib can be administered without any dose adjustment to Asian patients and, at a lower dose of 3 mg, to patients with severe renal impairment or end-stage renal disease and to patients with moderate or severe hepatic impairment.

Investigation of ixazomib is ongoing, in NDMM and as long-term maintenance therapy after ASCT or other induction regimens, and in combination with other agents in patients with RRMM. The results of these trials are awaited with interest and will be used to further define the role of ixazomib in the treatment of MM in terms of optimal combination regimens and therapeutic approaches in different patient populations.

In summary, ixazomib is an effective therapeutic option in the treatment of RRMM, which, due to its oral administration, limited additional toxicity, and the demonstrated feasibility of its administration in combination regimens, is likely to have an important role in the long-term treatment of patients with MM.
